Although the total salt content of the body is diminished, it does not follow that the salt content of the blood per cubic centimetre is lowered. This will depend on the loss of water relative to the loss of salt. There are three possibilities: (1) The loss of water is relatively greater than the loss of salt: (2) the loss of water is proportional to the loss of salt—i.e., the fluids excreted by the stomach and kidney are together isotonic; (3) the loss of water is relatively less than the salt loss. Under these circumstances the osmotic pressure of the blood will be diminished. Compensatory mechanisms are then brought into play, which have as their object the maintenance of the osmotic pressure by retention of substances normally excreted by the kidney. *It has already been seen that in alkalosis the* excess of plasma bicarbonate is excreted in the urine, but when the alkalosis is associated with a low osmotic pressure the excretion of this excess of alkali tends to lower the osmotic pressure still more. There are thus two abnormal conditions present, and that mechanism which helps to minimise one abnormality *is bound to accentuate the other: excess of base in* the blood requires the excretion of basic salts by the kidney, while lowered osmotic pressure calls for the retention of all salts, basic and otherwise. According to Hartmann and Smyth,[1] osmotic requirements are the more important, and base is retained by the kidneys, with an even greater increase in the plasma bicarbonate. *In such circumstances, however, the* acid products of metabolism still require to be removed, and they are excreted in the urine as such or in combination with ammonia. Therefore, in cases of pyloric stenosis when the osmotic pressure falls to a certain level, one would expect to find a further increase in the bicarbonate reserve of the blood and a change in the urinary reaction from alkaline to acid. Such findings are recorded in certain of Hartmann's cases, but in the present series they were exceptional. Thus, the sum of HCO_3 and Cl molarities was low in three cases and extremely low in four others, but in all these the urine was alkaline, while acid urines were associated with alkalosis in four cases, although the sum of HCO_3 and Cl molarities was only slightly below the normal figure.

Another possible means of maintaining the osmotic pressure of the blood is afforded by a retention of urea in the kidneys. Certainly, the blood-urea is often raised in congenital pyloric stenosis, but it has been noticed previously that the blood-urea does not bear a close relation to the sum of HCO_3 and chloride molarities. It is probable that both urea retention and base retention (with the excretion of an acid urine) depend on some factor in addition to the osmotic pressure of the plasma; possibly to deficient renal excretion. Thus, the loss of water from constant vomiting leads to profound dehydration and deficient circulation through the kidneys: this, in turn, might quite easily result in imperfect excretion of base (cf. Henderson and Palmer[8]) and of urea.

Reaction of the Blood.—The relatively small rise in pH associated with increase of the plasma bicarbonate must be explained by retention of CO_2. It is noteworthy that Graham and Morris[7] have observed that the respiratory exchange is diminished in these cases. This retention of CO_2 doubtless explains the infrequency of tetany in congenital pyloric stenosis.

Treatment.

Apart from the usual treatment with drugs and lavage it is necessary to administer large quantities *of fluid because of the dehydration. As alkalæmia* is present as well, no bicarbonate of soda should be given. It is probable that sudden death before and shortly after operation may be the result of alkalæmia, and this is more likely to occur if alkalis are being given therapeutically. Sodium chloride, on the other hand, is indicated, because it helps to limit the fall of chloride and rise of bicarbonate, and so tends to maintain the osmotic pressure of the blood. Indeed, copious saline infusions often bring about a striking improvement in the physical condition before operation, even in cases which at first sight appear quite hopeless. Probably it is worth while to delay operation in every case until about a pint of normal saline has been administered. If, however, it is not possible to introduce sufficient fluid, hypertonic saline (2 per cent.) may be used. Glucose may be combined with the saline, although this is not essential because of the rarity of post-operative ketosis.

following way. The blood-vessels of the blood-forming tissues are composed of histocytes (reticulo-endothelium) and the leucopoietic process occurs on the outer aspects of their boundaries. Piney says:

> "it may well be supposed that any injury to the vascular wall will permit immature leucocytes to escape into the lumen and so reach the general circulation."

This may be the initial lesion following the trauma, after which it is not hard to imagine that a compensatory productivity of the reticulo-endothelium becomes excessive and the process advances throughout the system. There is abounding evidence of the neoplastic nature of leukæmia, which is only one of the many existing types of malignant disease of the hæmatopoietic system—myeloma, chloroma, and (?) lymphadenoma.

All the cases of leukæmia following trauma have been of the myeloid variety; there is no evidence of a lymphocytic leukæmia or of an erythræmia beginning in the same way through proliferation of the corresponding type of cell. The explanation in the former case may be that the specific portions of the non-granular formative tissue are not strategically situated for that type of stimulus, and in the latter case that the red-blood forming tissue is not so susceptible to abnormal stimulation as is the white (granular) blood forming tissue.

Obviously, trauma cannot be regarded as the cause of all myeloid hyperplasia, and even in those cases where it is causative it is probably not wholly responsible. Traumata to susceptible regions occur every day and no one can avoid them, and yet such cases as are recorded here are remarkably rare. Some other factor must be at work and in all probability it occurs as a susceptibility to the disease, a predisposition or diathesis. It is only the predisposed who get the disease, just as only the predisposed have a sarcoma at the site of a former injury. Addison's anæmia has been shown to be due to an inherent abnormality which may be brought out in one of many ways; leukæmia can be placed in a similar class. Without the precipitating influence of trauma or some other influence, such as malaria or syphilis, the disease may or may not develop in the predisposed person. There is some evidence that this susceptibility may be inherited or it may merely be congenital. Piney writes: "it is probably rare for a congenital anomaly of the hæmatopoietic tissue to be so extreme as to result in manifest disease without the interposition of some further stimulus. Such environmental changes may be internal or external."

Finally, reference must be made to the medico-legal aspect of this type of case. In the German series a note about compensation was found in four cases. Three of the cases were awarded pensions on the assumption that the trauma received at work was responsible for the consequent illness. The fourth case was refused compensation. Compensation was refused by the courts in the present case.

My sincere thanks for his helpful advice are due to Dr. F. G. Crookshank, who kindly let me use the clinical records of his case, and to Miss D. Frazer and Dr. M. Friedeberger for their assistance in the translations of German and Italian references.

SOME FURTHER NOTES ON THE RELATION OF CAROTENE TO VITAMIN A.

BY E. M. HUME

AND

I. SMEDLEY-MACLEAN, D.Sc.

(*From the Departments of Experimental Pathology and Biochemistry, Lister Institute.*)

IT has been found by J. C. Drummond and co-workers [1] [2] that the yellow pigment carotene, even when crude, is not a very active source of vitamin A, and more recently it is claimed that with increasing purification biological activity is progressively lost.[3] On the other hand, H. von Euler, P. Karrer, and co-workers, [4] [5] T. Moore,[6] [7] and the present writers [8] have found carotene to be a very active source of vitamin A, in which the activity increases with increasing purification. None of these workers has been able to divorce the biological activity from the pigment while the latter remained intact. Notwithstanding this failure the possibility still remains that the pigment and the substance responsible for the biological activity, in material derived from plants, are distinct substances, so closely resembling one another as to defy separation by the methods as yet tried.

In discussing the remarkably divergent results summarised above, it was suggested both by ourselves [8] and by Moore [9] that the exclusion by Drummond of fat from the basal diet of the experimental rats might be a significant factor in contributing to the negative result obtained by him and his colleagues. Those workers who had found carotene active as a source of vitamin A had always included fat in the diet. We have, therefore, sought to compare the effect of administering purified carotene, as the sole source of vitamin A, to groups of rats on diets devoid of and containing fat.

In the upshot, the presence or absence of fat in the diet was not found to have significance, but the solvent employed, in order to avoid the use of a natural fat as flux, was found to have a most important influence.

Administration of Carotene to Rats on Diets Containing and not Containing Fat, but Equally Deficient in Vitamin A.

Six young black and white rats of about 40 g. weight were used for the experiment and were divided into two groups. Each group contained one rat belonging to one litter and two rats belonging to a second litter.

During the preliminary depletion period of the experiment all the rats received the following diet:—

Casein *	20	Marmite	4
Rice starch	72	Salt mixture * ..	4

Water was added to make a paste.

* British Drug Houses. "Fat and vitamin free."

Each rat also received daily one drop of ethyl oleate, containing 0·004 mg. of irradiated ergosterol, as source of vitamin D. The animals were kept in cages on fine wire screens. On this diet the rats grew poorly and were only slowly depleted of vitamin A.

On the sixtieth day in the case of one rat, and on the forty-ninth in the case of the other two, in one group, 16 parts of starch in the diet were replaced by 16 parts of hardened arachis oil. At the same time it was apparent that other modifications in the diet of both groups were necessary. The rats were seen to be failing for lack of vitamin B and were only saved by administration of a dose of dried yeast and by subsequently raising the amount of marmite from 4 parts to 15. So small an amount of marmite as 4 per cent. is certainly not reliable as a sufficient source of B-vitamins, although it is that commonly used by some workers. At the same time, in consequence of observations described later, the solvent for the irradiated ergosterol was changed from ethyl oleate to liquid paraffin.

When both groups of rats were becoming depleted of vitamin A, the carotene was administered daily in liquid paraffin; the daily dose per rat was 0·006 mg. For the first 22 days of administration the carotene was derived from spinach; when this material was used up, another batch derived from carrot was used; the latter was known from other tests to be of about the same biological value as the former and was used for the last 17 days of experiment. The carotene maintained its colour fairly well in the solvent though slow fading was apparent, but the dose of carotene selected, 0·006 mg., was chosen as being well above the known minimal dose (0·003 and 0·002 mg. respectively) for the two specimens of carotene used. There was thus a margin to allow for a gradual loss of potency and for a possibly only partial utilisation of the carotene from the solvent.

The two groups of rats were equally maintained in health throughout the 39 days of experiment; those which received fat in the diet actually grew slightly less than those which did not. It is thus shown that the utilisation of the carotene as a source of vitamin A was not dependent on the presence of fat in the diet. The details of the experiment are set out in the Table.

Growth of Rats on Diets Deficient in Vitamin A, to which 0·006 mg. daily of Carotene is added, as Source of Vitamin A, after a Preliminary Depletion Period.

GROUP I.—Diet Devoid of Fat. II.—Diet Containing Fat.

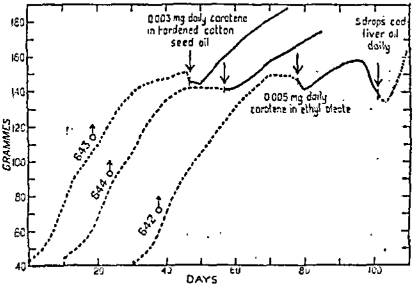
Behaviour of Carotene in Different Solvents.

The use of a natural oil as a solvent for the administration of vitamin A in biological tests has been strongly condemned by Drummond,[3] who recommends ethyl oleate as a suitable solvent.[2,3] We have always used hardened cotton-seed oil as the solvent in our tests on carotene and have found it very satisfactory; there is probably a very slow decolorisation of the carotene, even in this solvent. In view of the discrepant results already referred to, it seemed desirable to make use of ethyl oleate as a solvent and to examine the behaviour of carotene in it.

The biological technique used was that usually employed by us;[6] the diet included hardened cotton-seed oil and sufficient dried yeast to supply at least one gramme daily, even to rats consuming the minimum amount of food. The carotene was dissolved in ethyl oleate and the solution was kept in a corked bottle in the cold room when not in use. It was found that in these conditions the carotene was comparatively rapidly decolorised. Thirteen days after the solution had been made up the loss of colour was quite convincing and no positive biological result was obtained with carotene dissolved in ethyl oleate. The weight curves of rats set out in the accompanying chart have been selected to show a comparison between the behaviour of the same sample of carotene dissolved in ethyl oleate and in hardened cotton-seed oil, as a source of vitamin A. Rats 642 and 643 were males of the same litter; rat 644 was a male belonging to another litter. Rats 643 and 644, after being first depleted, received a daily dose of 0·003 mg. of carotene (melting point 172° uncorr.), derived from spinach and dissolved in hardened cotton-seed oil. Rat 642 received a larger dose, 0·005 mg., of the same carotene freshly dissolved at the beginning of dosage in ethyl oleate. From the chart it is seen that the two rats receiving the smaller dose of carotene, but dissolved in hardened cotton-seed oil survived the 28 days of the experimental period and grew well throughout. The rat which received the larger dose of carotene, but dissolved in ethyl oleate, grew a little for the first 17 days of the experiment, but then began to decline. When the loss in weight had amounted to 20 g. it was treated with cod-liver oil and recovered, showing that the failure had been due to a deficiency of vitamin A and to no extraneous cause. At the time when this rat began to decline in weight the carotene solution in ethyl oleate had passed from a deep orange to a light canary yellow.



Weight curves of rats on a diet deficient in vitamin A. After depletion period, treated with carotene, dissolved in either ethyl oleate or hardened cotton-seed oil.

The effect of various solvents in producing oxidation of carotene was therefore compared, the diminution in colour of the solution being taken as evidence of the progress of oxidation. Oleic acid (Kahlbaum), redistilled ethyl oleate, olive oil, and paraffin were chosen and 2·5 mg. of the pigment were dissolved in 2·5 c.cm. of each of these solvents and kept in open tubes. Solutions of potassium bichromate were made up matching in intensity of colour each of the solutions and were kept as standards for comparison. The paraffin solution was somewhat paler in tint than the three other solutions. A similar set of solutions was made up in tubes which were then evacuated and sealed. In another experiment after being evacuated the tubes were filled with nitrogen before being sealed. All the tubes were kept at room temperature.

The colour of the solution of carotene in oleic acid fell off rapidly in the tube open to the air and at the end of a week the solution was completely decolorised, while in the same period the colour of the ethyl oleate solution had diminished considerably in intensity, and before the end of four weeks the colour had completely disappeared. The solutions, both in paraffin and in olive oil, remained for several weeks without apparent change and then a slow falling off took place. After three months a solution of carotene in olive oil, which had been exposed to the air, was still yellow.

The contents of the tubes sealed after the removal of oxygen showed a rapid falling off in the intensity of the colour in the oleic acid and ethyl oleate solutions, after which the colour remained for a long time without further change. The initial fading is most probably due to the incomplete removal of all oxygen from the tubes. All the three solvents, oleic acid, ethyl oleate, and olive oil, contain the oleyl radicle; it is possible that the oxidising action may be due to the presence of a small amount of linolenic acid, which forms very readily a peroxide, by means of which oxygen would be rapidly passed on to any substance dissolved in it. This oxidising action is somewhat less in ethyl oleate and very much retarded in olive oil. There is, however, no evidence that the olive oil contains less linolenic acid than does the purified oleic acid or ethyl oleate. Possibly the determining factor is the degree of solubility of oxygen in the different solvents. The addition of hydroquinone (1 part in 100,000) diminished but did not prevent the oxidation of the carotene, both in oleic acid and in ethyl oleate solution.

Whether the oleic acid and ethyl oleate are to be regarded as acting as pro-oxidants, or the olive oil as acting as or containing an anti-oxidant, it is clear that the use of either of the two former solvents is quite unjustified when dealing with a substance as susceptible to oxidation as is the highly unsaturated substance carotene.

Conclusions.

The presence or absence of fat from the basal diet does not appear to be a factor of any importance in determining the biological activity of carotene.

The unsuitability of ethyl oleate as a solvent for carotene affords a sufficient explanation of the discrepancy between Prof. Drummond's results and those of other workers on the activity of carotene as a source of vitamin A. Whether this fact supplies the whole explanation it is not yet possible to say. So far as our experience goes there is at present no evidence available finally to decide the relationship between carotene and the substance responsible for the biological activity in vitamin A of liver extracts. It cannot yet be decided whether carotene acts as a provitamin, as Moore[10] has suggested, or whether carotene from all sources is always accompanied by a constant percentage of impurity, which up to the present has defied all methods to separate it.

We are greatly indebted for grants, respectively, from the Medical Research Council and the Department of Scientific and Industrial Research.

LIVER THERAPY IN ANÆMIA OF ALIMENTARY ORIGIN.

BY DANIEL T. DAVIES, M.D., B.SC.WALES, M.R.C.P. LOND.,
MEDICAL REGISTRAR, MIDDLESEX HOSPITAL.

IT is a well-established clinical fact that the anæmia resulting from cancer of the stomach does, in a certain small percentage of cases, resemble Addisonian anæmia. Text-books on medicine always include the differential features between these two conditions, and indeed without complete investigations it is sometimes impossible to arrive at a diagnosis. Gastric symptoms may be completely in abeyance, and the anæmia may dominate the clinical picture. The lemon-tinted skin, the anæmia, its symptoms and signs, with anorexia and flatulence, form a small but well-known clinical group of gastric cancer. While this possibility has been and is fully realised, the cause of such an anæmia has remained unexplained. Occasionally it has been attributed to the presence of secondaries in the bone-marrow, an explanation which has been found wanting in the majority of cases when they have been examined after death. Although hæmorrhage from the tumour site does occur and may be brought forward as a possible explanation of the anæmia, cases of marked anæmia are seen in which no bleeding can be demonstrated. While, therefore, the true cause of the anæmia has not been adequately explained, the advent of liver therapy, with its beneficial effect on primary anæmia, has renewed an interest in the relationship of these anæmias of alimentary origin to that of primary type.

Previous Observations.

Interesting observations have been recorded on some cases of gastrectomy for carcinoma, in which an anæmia has developed many years after the resection of the stomach and the autopsy showed no evidence of secondary growths, and no apparent cause for the anæmia. The oft-quoted examples are those of Moynihan[1] and Hartman.[2] While Moynihan's diagnosis was only clinical, Hartman's case showed a blood picture that resembled that of pernicious anæmia. The appearance of this type of anæmia following gastrectomy is, of course, rare and exceptional, for many surgeons have reviewed their series of gastrectomy and found no evidence of a primary anæmia, although a certain proportion of cases do show an anæmia of the secondary type. It is difficult to draw any conclusions from surgical cases, for gastrectomy is only a relative term, and in the majority does not mean total excision of the stomach—a procedure comparatively uncommon.

Dennig[3] reported quite recently the history of a man who had a gastrectomy performed on him in 1918 for a gastric ulcer who eight years later complained of paræsthesia and pain in the lower limbs.

The man showed pallor, a pale smooth tongue, ataxia of the lower limbs, diminished sensibility, and absent tendon reflexes. The blood picture was typical of pernicious anæmia: the hæmoglobin was 50 per cent.; red cells, 1,800,000; colour-index, 1·4; and white cells, 4800 (lymphocytes 65 per cent.). Anisocytosis was observed in the films. Four months' treatment with iron and arsenic and blood transfusions resulted in no improvement, the blood picture being: hæmoglobin, 35 per cent.; red cells, 1,400,000; and colour-index, 1·25. Megaloblasts were now present in the blood films. Liver therapy was commenced and the blood figures at the end of 14 days showed a hæmoglobin percentage of 60, and 2,300,000 red cells. Unfortunately, the man died of broncho-pneumonia 17 days after liver diet had been instituted.

Hochrein[4] also reports two cases of gastrectomy in which an anæmia resembling pernicious anæmia was found, and in both of which marked improvement followed liver therapy.

The first was a man, aged 55, who had had a gastrectomy for carcinoma eight years previously. The blood showed hæmoglobin, 45 per cent; red cells, 1,560,000; colour-index, 1·7; and white cells, 6600. Megaloblasts were seen in the films. The blood figures after liver treatment showed: hæmoglobin, 70 per cent.; red cells, 4,800,000; colour-index, 0·84; and white cells, 6600, with an eosinophilia of 19 per cent. His second case was a woman who had had her stomach removed for gastric ulcer nine years previously. The blood picture was that of a secondary anæmia: hæmoglobin, 43 per cent.; red cells, 3,420,000; and colour-index, 0·79. Here again improvement with liver was noticed, hæmoglobin rising to 85 per cent., the red cells to 4,460,000, and the colour-index to 0·9. Hochrein thinks that, with the history of gastrectomy and the response to liver therapy, the anæmia was the result of the gastrectomy.

Crohn[5] refers to one of his cases of syphilis of the stomach, in which subtotal resection had been performed, which developed a severe anæmia of the primary type several years after the gastrectomy. It is interesting that, according to Crohn, anacidity is rather characteristic of gastric syphilis. In 1924 Garvey and Stern[6] published a report of a case in which the symptoms and signs of subacute combined degeneration of the cord were obvious, and in which were found an achlorhydria, high colour-index (but no marked anæmia), atrophy of the mucous membrane of the tongue, and lemon-tinted skin. Not, however, until the post-mortem examination was the presence of a carcinoma of the stomach suspected. The histological changes of subacute combined degeneration of the cord were verified by section. In 1925 Ellis[7] reported the details of a case in which a man underwent a partial gastrectomy for a carcinoma in 1909, and 16 years afterwards presented signs of subacute combined degeneration of the cord with a sore tongue and a blood picture suggestive of pernicious anæmia.

Details of Five Cases.

The following are the details of five cases, four of carcinoma of the stomach and one probably of the pancreas, in which liver therapy was given and observed. In all the following features were present: a lemon-tinted skin, symptoms of anæmia, and achlorhydria.

Case 1.—A man, aged 56, complained of dyspnœa on effort, and a lemon-tint of the skin which would "come and go." He had no gastric symptoms, enjoyed his food, and in all respects felt normal, with the exception of some shortness of breath on exertion for three months. Examination showed a definite yellow pallor in a well-built man. Fractional gastric analysis showed an achlorhydria with rapid emptying and no evidence of obstruction at the pylorus. Enlarged glands were palpable in the left cervical region, and a barium meal revealed a large filling-defect extending along the posterior wall of the stomach. The blood examination showed: red cells, 2,800,000; hæmoglobin, 43 per cent.; white cells, 10,200; and colour-index, 0·7. The film showed the red cells to be poorly stained but with poikilocytosis and some red cells larger than normal. As the condition was regarded as inoperable and no surgical relief of obstruction was necessary, liver therapy was given, and the patient's response observed.

In 14 days the following figures were noted: red cells, 3,040,000; hæmoglobin, 44 per cent.; white cells, 6200; colour-index, 0·56. Two months after treatment the dyspnœa had completely disappeared, no anæmia was apparent, and the patient seemed to be better in every way. The count was then: red cells, 4,650,000; hæmoglobin 76 per cent.; white cells, 7600; colour-index, 0·84. A short time afterwards the gastric symptoms became obvious, the patient began to vomit and signs of emaciation rapidly advanced, and he died a few weeks after the onset of obstructive symptoms. This case, although by no means an anæmia of primary pernicious type, showed a definite response to liver therapy and had, in addition, as well as a marked anæmia, an achlorhydria and a rapidly emptying stomach.

Case 2.—A woman of 50 complained of dyspnœa, yellow appearance, and palpitations of five months' duration, with loss of weight noticeable for two months. Clinical examination disclosed a tenderness in the epigastric angle, a lemon-tint of the skin, and a complete achlorhydria with high total acid values, blood in the resting juice, and a stomach empty in one hour. The barium meal showed a filling-defect in the region of the pylorus and a rapidly emptying pyloric canal. Operation was advised but was refused. The blood at this time showed: red cells, 2,250,000; hæmoglobin, 45 per cent.; white cells, 6000; colour-index, 1·0. A film showed moderate anisocytosis and poikilocytosis but no nucleated forms. The patient was kept under observation and liver given in the diet. As this was easily tolerated, it was possible to observe the effect.

After liver.	Red cells.	Hæmoglobin percentage.	White cell.	Colour-index.
14 days ..	3,210,000	43	8,200	0·7
21 „ ..	3,560,000	45	6,800	0·6
28 „ ..	3,860,000	45	10,200	0·6
35 „ ..	3,500,000	46	8,400	0·6
42 „ ..	3,470,000	48	8,200	0·7
3 months..	4,380,000	42	10,000	0·5

While the red cells showed a definite increase, the hæmoglobin value remained stationary over this period. The subsequent history was the usual rapid downhill course, somewhat relieved by a gastro-enterostomy. Throughout the time of observation the stools contained occult blood, and it is somewhat remarkable that in spite of the persistent bleeding the red cells increased in number over a limited time, and that this increase was accompanied by definite improvement in the general appearance. This case again responded to a certain extent to liver therapy, and had, in common with the other, an achlorhydria and a rapidly emptying stomach.

Case 3.—A woman, aged 49, complained of sickness after food for three months, loss of appetite, and extreme shortness of breath. She had observed that her stools had been pale in colour and bulky. A lemon-tint of the skin had been commented on by her friends. She had lost weight and had for the last three months suffered from abdominal pain, made worse by the ingestion of food. Examination showed a definitely yellow colour, dyspnœa, and much anæmia. The subcutaneous fat was well retained and no œdema was obvious. The tongue was dry and glazed, with atrophy of the papillæ. Abdominal examination disclosed a large, hard mass in the lower abdomen, and a smaller one in the epigastrium. Gastric analysis showed a complete achlorhydria. A barium meal showed no gastric lesion. The urine contained 100 units of diastase, and bile-pigments were present; the icterus index of the blood was 25, and the van den Bergh reaction indirect. The stools contained excess of total fats, and the reaction for occult blood was negative. A definite diagnosis was not possible, but a tentative diagnosis of carcinoma of the pancreas was made, and as no surgical interference was contemplated, the patient was kept under observation.

The blood examination showed: red cells, 1,300,000; hæmoglobin, 26 per cent.; white cells, 7200; colour-index, 1·0. Four days after commencing liver therapy the patient became so dyspnœic and distressed that a blood transfusion had to be given. Œdema of the face and hands appeared, and the patient seemed to be in a critical state. Vomiting was so frequent and persistent that it was quite uncertain how much liver extract was absorbed. However, 13 days after commencing liver therapy the blood figures were: red cells, 1,650,000; hæmoglobin, 20 per cent.; white cells, 6000; colour-index, 0·7. Nucleated reds and some megalocytes were present, and one megaloblast was seen. Poikilocytosis and polychromatophilia were very obvious.

After liver.	Red cells.	Hæmoglobin percentage.	White cells.	Colour-index.
3 weeks ..	2,040,000	31	—	0·8
4 „ ..	2,800,000	48	7000	0·9
5 „ ..	3,670,000	60	6100	0·84
7 „ ..	3,700,000	60	4600	0·8
8 „ ..	4,300,000	62	6000	0·82

At this time, eight weeks after the institution of liver therapy, the patient looked well, there was no dyspnœa, and no obvious anæmia. The digestive disturbances were as before, and the abdominal masses were palpable. In this case no occult blood was found in the stools, and no evidence of a bleeding-point was found at any time. The diagnosis of cancer has not been verified, but what is known is that this patient, like Cases 1 and 2, had an anæmia associated with an achlorhydria, showing evidence of a malignant condition of the abdomen, and that this anæmia showed a rapid improvement on a diet of liver extract. The blood films, although showing a superficial resemblance to pernicious anæmia, did not resemble the primary type, nor did the red cells and the hæmoglobin proportion. However, the lemon tint of the skin, the atrophic tongue, the achlorhydria, and the rapid response to liver extract, suggest that it was an anæmia in some ways analogous to that of pernicious anæmia.

Case 4.—A man, aged 56, was seen only nine days before death. He had always enjoyed good health, and had complained of weakness and shortness of breath for only six weeks. For two weeks before he sought advice he had suffered with pain in the left side of the abdomen. Diarrhœa had been present for one week and anorexia for six weeks. He had never vomited. He was extremely pale with an icteroid tint, very emaciated, and dyspnœic. The distended abdomen contrasted markedly with the wasting of the rest of the body, and a hard mass was palpable in the epigastrium. No œdema was present, and no organic nerve signs were elicited. A gastric analysis showed complete achlorhydria, and a resting juice foul in smell with a total acid value of 34. A diagnosis of carcinoma of the stomach was made. Examination of the blood showed: red cells, 1,300,000; hæmoglobin, 30 per cent.; white cells, 12,000; colour-index, 1·15. The red cells were well stained and varied in size; numerous megalocytes were present, and one or two megaloblasts were noted. Poikilocytosis and polychromatophilia and an eosinophilia of 4 per cent. were present. Liver extract was given. One week later the blood count was: red cells, 1,340,000; hæmoglobin, 30 per cent.; white cells, 11,000; colour-index, 1·2. The patient did not improve but became more dyspnœic, and died in nine days. Post-mortem examination showed a hard growth of the pylorus extending along the lesser curvature and the posterior wall of the stomach. Secondary deposits were present in the liver, but no bony deposits were found. The bone-marrow was red throughout, and showed an erythroblastic reaction resembling that seen in pernicious anæmia. The death of the patient prevented observation on the effect of liver therapy, but here again the achlorhydria was associated with profound anæmia which, in this case, apart from the leucocytosis, was indistinguishable from that seen in pernicious anæmia.

Case 5.—A man, aged 57, had suffered from anæmia for four years with indefinite anorexia for six months and showed signs of wasting and of œdema. He had no vomiting or bleeding. There was a marked lemon-tint of the skin with pallor of mucous membranes. Œdema of the feet, abdominal wall, hands, and elbows was present. A fractional gastric analysis showed a resting juice with a high total acid value, of bad odour and large in volume with complete achlorhydria. Occult blood was present in the fæces. With such an advanced state no interference was contemplated, the patient being too ill even to be radiographed. The blood examination showed: red cells, 1,900,000; hæmoglobin, 17 per cent.; white cells, 7400; colour-index, 0·4. Anisocytosis and poikilocytosis were marked in the blood film, but no nucleated forms were observed. Liver extract was given, and 14 days later the following figures were noted: red cells, 2,100,000; hæmoglobin, 16 per cent.; colour-index, 0·4. The patient unfortunately died quite suddenly four days afterwards, and 18 days after the commencement of liver therapy. Whether a response would have been forthcoming had the patient lived remains undecided. Post-mortem examination showed a large, hard growth at the pylorus, with a softer extension along the posterior wall of the stomach, secondary deposits in the lymphatic glands, and an erythroblastic reaction in the bone-marrow. No secondaries in the bone-marrow were discovered. This case of carcinoma ventriculi, therefore, showed an achlorhydria associated with a marked anæmia in which the gastric symptoms were in abeyance, but in which the response to liver therapy remains problematic.

Comments.

In pernicious anæmia the constancy of achlorhydria is one of the most valuable diagnostic features. While Faber[8] and Hurst[9] have always held the view that the achlorhydria, or rather achylia gastrica, is the essential basis for the development of this anæmia, definite direct proof of this has been lacking until the recent work of Castle,[10] who has shown that an equally good response to that obtained by liver therapy can be secured in cases of pernicious anæmia if they are given beef that has been predigested with normal human gastric juice. By experiments of exclusion he has shown that it is not the hydrochloric acid nor the pepsin (at least commercial pepsin is inactive) in the gastric juice that is the active principle, but some other unknown factor present in healthy gastric juice. This substance, according to Castle's view, presumably present in normal gastric juice only, is able, by its action on beef muscle, to produce some agent which is capable of acting as efficiently as liver in bringing about a remission in pernicious anæmia; and he believes this to be the factor which, in some unknown way, prevents the development of pernicious anæmia in normal persons. This work is of profound interest for, if it is confirmed, it will make the relationship of achylia and pernicious anæmia one of more than diagnostic importance. It will become of ætiological significance. It will also bring into line the anæmias that have been observed following gastrectomy and those observed in carcinoma of the stomach. The ready response to liver in these, as distinct from other secondary anæmias, supports the conception that there is a relationship between these anæmias and pernicious anæmia, and, in addition, that the development of pernicious anæmia is the sequel to a defective gastric secretion.

If pernicious anæmia is so closely related to gastric secretion, and if its advent is dependent upon achylia, it may be asked why a primary anæmia is not more frequently seen in cancer and gastrectomy cases. The reason may be the difference in time; pernicious anæmia is an insidious disease and achylia has been noted in some cases many years before the development of any anæmia, while in cancer it is rare for the patient to be alive for more than two years after the symptoms of anæmia have become obvious. Again, investigations on cases of gastrectomy have shown that some gastric secretion always takes place, even if there is no free hydrochloric acid, a sufficient amount of gastric mucosa being left to produce some secretion. For this reason the underlying secretory disturbances can hardly be regarded as identical in pernicious anæmia and gastrectomy. The five cases given in this paper showed an achlorhydria associated with an anæmia, and three responded to liver therapy. Their ready response to liver brings them into line with pernicious anæmia, and emphasises the common factor—a deranged gastric secretion. The two cases that died showed a bone-marrow similar to that seen in pernicious anæmia, thus still further emphasising the similarity.

From a study of the literature and the foregoing cases the response of certain types of anæmia of gastric origin to liver therapy seems to be comparable to that of the primary anæmia. Two conclusions naturally follow from this: first, improvement through liver therapy in cases of anæmia associated with achlorhydria is not diagnostic of pernicious anæmia: secondly, liver therapy may prove of therapeutic value in gastric conditions, in pre- and post-operative periods, in which there is an anæmia associated with an achlorhydria, although the blood count be not of the pernicious or primary type.

The writer wishes to record his thanks to Prof. A. M. Kennedy and Dr. G. E. Beaumont for their kind permission to investigate some of the cases herein recorded, and to Dr. Lionel Whitby for helpful advice and criticism.

A NEWCASTLE WAITING LIST.—In support of their appeal for £150,000 for enlargement, the Governors of the Royal Victoria Infirmary, Newcastle-on-Tyne, state that the waiting list contains nearly 3000 names, and that the Infirmary has "become, without exception, the most overcrowded hospital in Great Britain." Almost every week close upon 100 additional beds have to be placed between others in the wards to admit accidents and urgent cases. Whereas in 1906 the in-patients were 4899, in 1929 they numbered 14,460. In the same period the out-patients have grown from 50,000 to 355,000, and operations from 4000 to well over 12,000.

ANÆSTHESIA FOR THORACOPLASTY IN PULMONARY TUBERCULOSIS.*

BY I. W. MAGILL, M.B. BELF.,
ASSISTANT ANÆSTHETIST TO WESTMINSTER HOSPITAL; ANÆSTHETIST TO THE HOSPITAL FOR CONSUMPTION, BROMPTON.

FROM the anæsthetic standpoint, thoracoplasty and similar operations on the tuberculous subject differ a good deal from operations performed on the patient with a normal respiratory mechanism. I propose to give briefly my observations in some 300 anæsthetics for this type of operation alone.

Condition of the Patient.—Operation is only decided upon when medical measures have failed to arrest the disease. The patient has therefore had toxæmia for a considerable period from tubercle and its attendant secondary infection. The vital capacity is below normal and the blood pressure frequently low. There is often physical exhaustion from the ever-recurring effort to cough up accumulations of sputum. It is apparent, therefore, that recovery from any operation undertaken to aid in arresting the disease should not be hampered by the effects of the anæsthetic. At the same time, it must be remembered that such operations are not in the nature of emergencies. The patient has been under the care of the physician, who has made every effort to secure the best possible physical condition before operation. Vital capacity and blood pressure readings are taken, and before the patient comes to the theatre he is placed for a time in the position which enables him best to clear his lungs of sputum.

Requirements of the Operation.—The surgeon requires the patient in the lateral position, the healthier side of the chest being supported by an air-cushion. This position is not an easy one in which to keep a mask air-tight on the patient's face or in which to control the air-way. There is a tendency also for the movements of the lower side of the chest to be impeded, although the position of the air-cushion in the axilla allows a certain amount of free expansion at the pulmonary base. The operation involves the exposure of a wide bleeding surface in a patient whose resistance to shock and hæmorrhage is strictly limited. Muscular relaxation is not absolutely essential, however, and deep anæsthesia is therefore unnecessary. The time required for operation is short, the average being 25 minutes.

Choice of Anæsthetic.

Having considered the condition of the patient and the nature of the operation, it is apparent that the anæsthetic must fulfil certain requirements, which may be classified as follows: (1) Recovery should be rapid in order that any accumulation of sputum be actively expelled immediately after the operation. (2) For the same reason the cough reflex should be present during the progress of the operation. (3) There should be no irritation or damage to the patient's lungs, either immediate or remote. (4) The anæsthetic should not cause post-operative acidosis. It is obvious that ether and chloroform should be omitted if it is possible to use less toxic agents. There remain at the disposal of the anæsthetist local analgesia, on the one hand, and general anæsthesia with nitrous oxide and oxygen, or ethylene, on the other; or a combination of the two. I shall briefly consider the merits and disadvantages of each.

Local Analgesia.—The advantages are: (1) It causes no irritation or damage to the lungs. (2) It causes no post-operative vomiting or acidosis. (3) There is definitely less bleeding during the operation. The disadvantages are: (1) The length of time required for extensive infiltration. (2) The possibility of immediate toxic symptoms following the injection of considerable quantities of novocain. (3) A slightly greater tendency towards delayed healing and sepsis of the wound. (4) The undesirability of extensive rib resections in a conscious patient, from whom it is difficult to conceal this essential part of the operation.

General Anæsthesia with Nitrous Oxide and Oxygen.—The advantages here are: (1) An unconscious patient. (2) The attention of the surgeon being undivided the operation is consequently of shorter duration. (3) Recovery is rapid. (4) There are no toxic effects. The disadvantages are: (1) The necessity of a preliminary narcotic. (2) The difficulty of administering nitrous oxide and oxygen with a mask to a patient in the lateral position. (3) A certain degree of sub-oxygenation is necessary sometimes to obtain anæsthesia. (4) There is more hæmorrhage than with local analgesia.

Discussion.

It is obvious that each of the anæsthetics mentioned has certain factors to commend it. I am aware that local analgesia is the routine for thoracoplasty in many continental clinics, and to some extent in this country, but think it should be employed only when the operation is a minor one involving the resection of one or two ribs. There may be special instances in which local analgesia is preferable—for example, in a patient of suitable temperament or where a general anæsthetic is definitely contra-indicated—but I am convinced that there is less liability to shock when thoracoplasty is performed on the fully unconscious patient. As a rule a general anæsthetic is demanded by the patients themselves.

In referring to the disadvantages of general anæsthesia with nitrous oxide and oxygen, I have mentioned the necessity of a preliminary narcotic. It is well known, of course, that satisfactory anæsthesia with nitrous oxide and oxygen can only be obtained with the aid of efficient preliminary medication. Some physicians hold that the administration of a drug which may act as a respiratory depressant and sedative is undesirable for a patient secreting a large amount of sputum. In theory this may be correct, but cough being one of the troublesome symptoms from which these patients suffer, it may be assumed that most of them have tried every available remedy to alleviate it. This may account for the fact that, in my experience of these cases, I find they tolerate morphia well. It is my custom to give an adult omnopon gr. 1/3, and scopolamine gr. 1/150, and I have observed no ill-effects from this injection. While dealing with this point, I might mention that paraldehyde or avertin per rectum are contra-indicated in cases of this type, because it is essential that the patient should clear his lungs of sputum as soon as possible after the operation.

The difficulty of maintaining a mask in position on the patient's face can be overcome to a great extent with the aid of a rubber contrivance such as that devised by Dr. R. J. Clausen for the purpose. This difficulty, and with it the complete control of the patient's airway, could be easily dealt with by employing endotracheal anæsthesia, but I am of opinion that this method is contra-indicated in thoracoplasty. Intubation requires a deeper initial anæsthesia and a deeper maintenance level to keep the cough reflex in abeyance, while the tube is in the trachea, than is desirable in these operations. Deeper maintenance level also means the addition of ether or chloroform if an undesirable degree of cyanosis is to be avoided. This militates against a quick recovery, which, as I have already pointed out, is essential in these cases. With regard to sub-oxygenation in connexion with nitrous oxide and oxygen, I feel sure of the antagonism of physicians to its occurrence in any degree. Deliberate sub-oxygenation in the presence of a free air-way, however, is a very different matter from cyanosis due to respiratory obstruction, and it is on the latter that most fears are founded. The fact remains that the degree of sub-oxygenation produced is not dangerous and has no after-effects, as far as can be ascertained.

---

* A paper read before the Tuberculosis Association on Jan. 17th.

Anæsthesia can be maintained with 10 per cent. to 20 per cent. oxygen in most cases.

The relative increase in hæmorrhage in general anæsthesia as compared with local is counterbalanced by the increased coagulability of the blood. Hæmorrhage is easly controlled and there is no tendency to recurrence.

Conclusions.

At the Brompton Hospital, where most of my experience has been gained while working with Mr. Tudor Edwards, we have found that the best results are obtained with nitrous oxide and oxygen anæsthesia combined with block of the intercostal nerves as soon as the ribs are exposed. The injection by the surgeon of 1 c.cm. of 1 per cent. novocain in the region of each nerve takes but a few seconds and the total quantity injected is small. It has been observed that there is less liability to shock when the ribs are divided after nerve-block than when the injection is omitted.

We have kept anæsthetic records of all cases, and the results with this combined method have given cause for satisfaction. Of 101 thoracoplasties, representing 202 operations performed by Mr. Tudor Edwards on tuberculous patients, the operative mortality has been five, all occurring in the first three weeks after operation. One patient died on the third day from pulmonary embolism; one died on the sixth day from acute spread of the disease on the opposite side; one on the twentieth day from tuberculous pneumonia in the opposite lung; one on the eighth day after the second stage from syncope; and the last from tuberculous pneumonia on the fourth day.

We preserve an open mind upon the matter of anæsthesia, however, and I have used ethylene instead of nitrous oxide with a view to obtaining better results. So far, I have not found ethylene to be vastly superior to nitrous oxide. It is true that anæsthesia can be maintained with a greater percentage of oxygen when using ethylene—an undoubted advantage. But the objectionable smell of the gas and its explosive qualities have deterred us from further experiment.

Clinical and Laboratory Notes.

PURPURA AS A SOLE SIGN IN A CASE OF MENINGOCOCCAL SEPTICÆMIA,

WITH NOTES OF ITS INCIDENCE OTHERWISE.

By J. A. G. Burton, M.B., F.R.C.S. Edin., D.P.H.,
SENIOR ASSISTANT PATHOLOGIST, ROYAL INFIRMARY, GLASGOW;
AND
D. K. M. Chalmers, M.B., Ch.B. Glasg.,
RESIDENT ASSISTANT PHYSICIAN, ROYAL INFIRMARY, GLASGOW.

THE patient, a tram-driver aged 30, was at work as usual on April 12th, 1929, and seemed in his usual health.

On April 13th he went to work without making any complaint, but an hour later—viz., 8.30 A.M.—he returned home, as he felt sick and shivery. Shortly afterwards he vomited some black material and passed a black motion. In the afternoon he noticed that a rash had appeared upon his body. The sickness continued and he complained of coldness and pains in the legs and feet. A doctor was consulted and at once sent him into hospital, where he arrived at 1·30 A.M. on the 14th.

On admission he was found to be a well-built man. He was quite clear mentally, but very collapsed. The skin was clammy and covered with a deep purpuric rash, which affected the whole surface, head, trunk, and limbs, and was most marked on the back. The hæmorrhages varied in size from a pin-point to a blotch as large as half a crown. The skin surface was dusky and the lips were deeply cyanosed. No urine was obtainable. His temperature was 102·5° F., the respirations were regular, shallow, and frequent, and his pulse, which numbered 120 beats a minute, was very small and soft. He was very *thirsty, and shortly after admission vomited a small quantity of blood, both fresh and altered. The pupils were small* and equal, and responded to light. There was no retraction or stiffness of the neck, and Kernig's sign was negative.

He did not respond to treatment; the cyanosis increased and fresh petechiæ made their appearance, the pulse failed, and he died at 2·45 A.M.—less than 19 hours after the onset of his illness.

Post-mortem Examination.—There was a diffuse hæmorrhagic rash over the whole body, including the conjunctivæ. A few subpleural ecchymoses were scattered over the lungs, and subendocardial purpuric spots were present in all the chambers of the heart. The stomach and intestine showed some submucosal hæmorrhages. The meninges were congested, but no excess of cerebro-spinal fluid was found, nor was it unduly turbid. A lumbar puncture was done before the cord was exposed. On examination of this a few Gram-negative diplococci were found. On sectioning the brain nothing of note was found apart from superficial congestion.

This case is interesting on account of the fulminant nature of the symptoms and the predominance of the hæmorrhages. It is, of course, well known that in meningococcal infections death may ensue within a short period of the initial symptoms. Herrick[1] states that "death may occur within four to twenty-four hours of onset." Foster and Gaskell[2] quote the type of case where a man had gone to bed apparently in his usual health and was found dead in his bed in the morning; Worster-Drought and Kennedy[3] give an instance where a man was quite well all day and became ill in the evening; in the morning he was delirious and died half an hour after admission to hospital. These cases, however, are unusual.

The name "spotted fever" denotes the frequency with which hæmorrhagic eruptions occur in this disease, but hæmatemesis and melæna are rarely met with and hæmaturia is also uncommon. The following list shows the relative frequency of the causes of hæmorrhagic eruptions as met with in medical wards. During the last twenty years 73 cases in which a purpuric rash was a prominent feature were admitted into the unit. The clinical diagnosis in these patients was as follows: 32 cases might be grouped as septicæmia (bacterial endocarditis 27, cerebro-spinal fever 2, erysipelas, pyæmia, sepsis following burns, 1 each); 7 were leukæmias; 2 pernicious anæmia; 1 scurvy; 1 hæmophilia; 1 acute nephritis; 2 were associated with arterio-sclerotic disease, 1 with debility, and 1 with trauma. The remaining 25 cases were examples of "purpura," 9 of which died in the wards. In five of these nine cases post-mortem examinations were conducted and revealed no further cause of death. (No platelet counts were done.)

A Classification of Purpura.

In consideration of the foregoing cases the following classification of purpura was compiled from various sources. The condition may be defined as "spontaneous hæmorrhages into the skin, mucous membranes, and organs; with or without hæmorrhage into the mucous canals." Beware of flea-bites!

Group 1. (*a*) Purpura hæmorrhagica: the blood platelets are deficient; (*b*) purpura simplex: ? cause. (*c*) purpura rheumatica: purpura abdominalis: anaphylactoid purpura, possibly an intoxication due to histamine-like substances.

Group 2. *Secondary Purpuras* may be due to (*a*) chemical poisons—e.g., potassium iodide, mercury, arsphenamine, benzol, and snake poison; (*b*) infections: subacute bacterial endocarditis, cerebro-spinal fever, small-pox, and scarlet fever; the hæmorrhagic forms of the exanthemata, black measles, malignant scarlet fever, hæmorrhagic diphtheria, and hæmorrhagic small-pox; (*c*) cachexias, severe anæmias, and leukæmias; (*d*) mechanical causes: convulsions, whooping-cough, and senility; (*e*) nervous lesions: tabes dorsalis.

Group 3. *Scurvy.*—Due to the absence of water-soluble "C" vitamins.

Group 4. *Hæmophilia.*—The coagulation of the blood is delayed, due to a delay in the formation of the thrombin (hæmorrhagic disease of the new-born).

Group 5. *Fibrinopenia.*—Due to a complete lack of fibrinogen.

Our thanks are due to Dr. John M. Cowan, Royal Infirmary, Glasgow, for his advice and supply of clinical material and records.

SUBLINGUAL DERMOIDS.

BY RICHARD WARREN, M.D., M.CH. OXF., F.R.C.S. ENG.,
SURGEON TO THE WESTON-SUPER-MARE HOSPITAL;
AND
N. CARWARDINE COOPER, M.R.C.S. ENG.,
ASSISTANT SURGEON TO THE HOSPITAL.

THERE is still some uncertainty about the origin of sublingual dermoid cysts, and, according to Colp,[1] they may belong to one of two groups. The first he considers not to be true dermoids, as they do not contain the appendages of true skin. The second group includes the true dermoids, and may originate either (1) as epithelial "rests" from the tuberculum impar, or (2) from the union of the first and second branchial arches. Colp states definitely that the median thyroid Anlage (tractus thyroglossus) "can never give rise to true dermoid tumours."

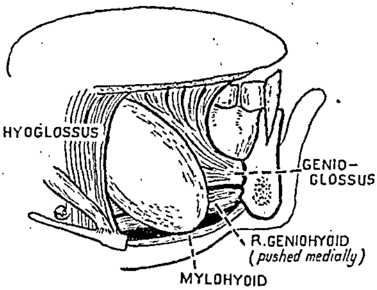

Diagram showing position of the cyst.

These true dermoids have been divided by Barker, Streickheisen, Marchant, Debonnelle, Lannelonge, and others into various sub-varieties, chiefly median and lateral. The latter lie between the latero-inferior aspect of the tongue and the mandibular ramus, above the mylohyoid muscle. The median variety are more truly sublingual in position. Median cysts may be further subdivided according to whether they are above or below the geniohyoid muscle. These cysts are probably present congenitally, but become more pronounced in early adult life when the epithelial tissues—hair, sweat, and sebaceous glands—become more definitely active. Some authorities consider the increase in size to be due to a low-grade infection, but Colp finds the contents to be uniformly sterile. Clinically they may either encroach into the floor of the mouth, where they must be distinguished from ranulæ or angiomata, or they may bulge as painless swellings in the submental region, where a further differentiation from lipoma is necessary.

They are sufficiently uncommon, judging from the literature on the subject, to warrant the publication of this case.

A boy of 17 complained of a swelling in the floor of the mouth and below the chin; it was inconvenient but caused no great difficulty in swallowing. Some months before a surgeon had made an attempt to deal with the condition through the mouth but without success. On examination there was a soft median swelling below the chin, and inside the mouth there was a smooth, fluctuating swelling below the tongue, which was pushed back. The two swellings were evidently continuous. The swelling in the mouth was median and faintly yellow in colour, suggesting a dermoid cyst seen through the mucosa of the sublingual region.

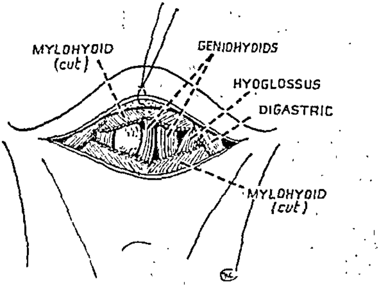

Diagram of dissection. The cyst is seen between the severed portions of the mylohyoid muscle.

A transverse incision was made midway between the chin and the hyoid bone; the right digastric was retracted and the mylohyoid divided transversely. The right genio-hyoid muscle was then pulled forward and the yellow cyst exposed, covered by the thinned and spread-out fibres of the geniohyoglossus. These last were dissected off readily, and the cyst, which extended up and far back into the tongue, removed intact. The mylohyoid was sutured and the wound closed with a temporary drain; it was well healed in a week.

The cyst was ovoid in shape and about 2½ by 2 in. in size. The wall was thin and lined with epithelium, and the cyst contained the usual porridge-like, acid-smelling material found in dermoids, but without any hairs.

MULTIPLE CARCINOMATA OF SKIN IN A CHIMNEY SWEEP.

BY W. DONALD BEDFORD, M.B. LEEDS,
RESIDENT SURGICAL OFFICER, HERTFORD COUNTY HOSPITAL.

A PATIENT, aged 45, attended the Hertford County Hospital in June, 1929, complaining of an ulcerated swelling of the lower lip (outer quadrant). He had been a chimney sweep for 20 years and had had the tumour on his lip for three months; it had discharged and occasionally bled when scratched. The tumour had an indurated edge and a central ulcer which bled easily when the scab was removed; there were no palpable glands. A V-shaped excision was done, and the lip healed normally (pathological report: epithelioma). He was sent to the Radium Institute, London, where radium was applied over the submaxillary region.

The patient reappeared at the hospital at the beginning of November, and he now complained of a similar tumour on the left side of the scrotum; it had been preceded by an eczematous condition of the skin of the scrotum of varying severity for some months. On examination the tumour presented an extraordinary similarity to the original tumour on the lip, both in colour and appearance. There were no palpable glands in either groin. The tumour was excised and pathological report showed it to be a growth of the same type as the one previously excised.

I have to thank Mr. Harold Medlock, senior surgeon to the hospital, for allowing me to publish this case, which was under his care.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

AT a meeting of this Society in London on Jan. 31st, with Dr. FRANCIS J. COUTTS, the President, in the chair, Lieut.-Colonel E. T. BURKE (Manchester) read a paper on the

TREATMENT OF WASSERMANN-FAST SYPHILIS.

He said that in considering the problem of Wassermann-fast patients it must be taken for granted (1) that the diagnosis of syphilis was correct; and (2) that the patient had received treatment of such quantity, quality, and duration as experience had shown usually to have the effect of rendering the serology permanently negative. What criteria were to be adopted for each of these two things? For the present, he thought, a positive Wassermann must be taken as the criterion of diagnosis; and a persistently positive result in a treated patient as an indication of uncured syphilis. One could go further, and reason that a persistently positive serology points to the fact that the treatment given to that particular patient has in this instance been inadequate. While a persistently positive serology in a treated case undoubtedly indicated uncured syphilis, a negative serology in such cases did not necessarily imply that the disease had been eradicated. Warthin's experience (see THE LANCET, 1929, ii., 556) seemed to show that the attainment of a negative W.R. seldom meant that the patient was cured. It was necessary to look well beyond the permanent negative, and find an answer to the question of how far beyond that must treatment be pushed in order to sterilise the patient's tissues. It seemed clear that the answer must be provided by the histologist and not by the serologist.

Colonel Burke emphasised the need for "checking up" autopsy findings in treated syphilitics against the treatment given during life. He believed that with proper handling cases of early syphilis, at least, could be cured not only clinically and serologically, but also histologically; in other words, that the human body could be completely sterilised so far as the *Treponema pallidum* is concerned. That was the ultimate objective of treatment, but for practical purposes at the moment it was necessary to rely upon the Wassermann test. The very least that should be aimed at was to render our cases permanently negative. Unless the postulate was accepted that a positive Wassermann meant syphilis requiring treatment, then the discussion could not even begin. Two classes of case came within their purview: firstly, there was the syphilitic whose serological reaction immediately after treatment was negative, but after a variable interval again became positive (Wassermann-relapse). Secondly, there was the syphilitic whose serum at no period ever receded into a negative (Wassermann-fastness).

The various opinions on treatment might be grouped into two schools: (1) that which, using arsenobenzol compounds and bismuth (or mercury) administers these concurrently; and (2) that which, using the same remedial agents, administers them in alternating series. Col. Burke belonged to the latter school. He had distributed among those present the schemes of treatment adopted in his clinic for (1) early, (2) late syphilis. Among cases of early syphilis treated according to these schemes, there had not yet occurred a case of Wassermann-fastness. In his view if chemical stimuli were applied too strongly, too often, or over too long a period, the reacting tissue might become exhausted. He was therefore in agreement with those who hold that the administration of arsenobenzol alone is essentially wrong. He agreed that the patient must be treated with bismuth as well; but he did *not* agree that the two agents should be given at the same time. By the properly spaced out alternating method, no chance was given to the tissues to become exhausted, and no chance to the treponemata to develop an immunity to the toxalbumin.

Colonel Burke proceeded to consider the matter of treatment, not only of the Wassermann-fastness, but of the Wassermann-fast patient. The first principle to be adopted was to change the mode of attack. And an essential preliminary to that was to rest the tissues. Three months' rest was not time lost; it was essentially a saving both of time and of material. During this rest period the patient should be carefully examined in order to discover the location of the main damage. The result of this examination might be such as to contra-indicate any further antispecific treatment; for example if a serious cardiovascular lesion was present. It might well be that in an elderly man the fibrosis which exists in his aorta may be the only rampart between him and death. The breaking-down of this by iodides might actually precipitate his decease. Such lesions might contra-indicate intravenous medication with arsenobenzol compounds; and so if these compounds were to be given, they must be of the type of sulfarsenol and the route must be intramuscular or subcutaneous. The discovery of the principal site of the disease might call for the exhibition of bismuth alone. The age and circumstances of the patient may be such that treatment is not required—that the patient would not live long enough to enable cure or reduction in the strength of the serological reaction to take place. In any case treatment should be controlled by serological tests which showed fairly fine gradations of the strength of the reaction. In every case of syphilis the exhibition of iodides was called for, except in late and grave cases of cardiovascular involvement. In Colonel Burke's view it was practically useless to give potassium iodide in doses of less than 90 grains a day. Iodides alone had no curative value—they were merely to be used as solvents of fibrous tissue, and to open up the way for the action of arsenicals and bismuth. In his experience the Turkish bath had a distinct value in such cases. There seemed to be at least two factors at work—stimulation of the skin and pyrotherapy. Non-specific protein therapy had a practical bearing upon the treatment of Wassermann-fastness, and should invariably be carried out. The time selected for this should be during the rest-period, before the resumption of truly antispecific treatment. The preparations which he used in his clinic were aolan—a sterile milk protein given intramuscularly—and dmelcos, which was a vaccine prepared from Ducrey's bacillus and given intravenously. The effect of aolan might be provocative.

Colonel Burke summarised his views as follows: (1) Wassermann-fast syphilis is most easily prevented by combined therapy with arsenic and bismuth administered in alternating series over a sufficient period. (2) Under this system, previously untreated cases of early syphilis will be serologically cured in a period varying from 24 to 40 weeks, according to the stage of the disease. (3) Wassermann-fastness implies the presence of living treponemata and structural visceral damage of a progressively fibrotic character. (4) The condition springs from exhaustion of the patient's tissues and the development of resistance by the treponemata. (5) Treatment begins with prevention—avoidance of tissue exhaustion and drug resistance. (6) The actual handling of the established condition implies: rest and rejuvenation of the tissues; elimination of previous storage depots; dissolution of treponemal fibrous-tissue defences; stimulation of natural immunity processes by injection of non-specific protein, and by general tonic treatment; and finally when antispecific treatment is recommenced agents should be adopted which have not previously been used, and they ought to be applied in alternating series.

Treatment and Subsequent Neuro-syphilis.

Colonel L. W. **Harrison** referred to Colonel Burke's opinion that concurrent administration of arsenobenzol and bismuth or mercury led to Wassermann-fastness. A much more important question was whether the alternating courses of these remedies in early cases led to more neuro-syphilis. Colonel Harrison felt strongly that they did. It had been stated that the modern treatment of syphilis led to more and earlier neuro-syphilis, and an inquiry had been made to discover if many of the survivors of the 100,000 soldiers treated for syphilis during the late war had been seen later at neurological or venereal clinics, in pensions hospitals, or in certain mental hospitals suffering from neuro-syphilis. No evidence had been gained in support of the idea that neuro-syphilis had increased under modern methods of treating syphilis, for only six cases had been found. But there was no smoke without some fire, and he had been trying to discover how the treatment given to syphilitic soldiers during the war differed from that given to patients of syphilologists who maintained that modern treatment increased neuro-syphilis. He thought the difference lay in the fact that the soldiers were treated on the concurrent plan. Alurralde and Sepich [1] were strongly of opinion that neuro-syphilis had increased in Brazil, and attributed it to the common practice of using arsenobenzol compounds exclusively. Weatherby,[2] in a paper on the previous treatment of 280 patients who had developed neuro-syphilis, found that of the five whose treatment had begun in the primary stage all but one had received arsenobenzol alone, while the single exception had had arsenobenzol with only three doses of mercury. Out of nine treated in the secondary stage, four had had arsenobenzol only and one mercury only. Bernard [3] had tested the cerebro-spinal fluid of 200 patients and related the findings to previous treatment. The fluid had been pathological in 75 out of 89 treated with arsenobenzol only; in 14 out of 34 treated with alternating courses of arsenobenzol and mercury; and in only 3 out of 42 cases treated with arsenobenzol and mercury concurrently. In the analysis of cases treated at St. Thomas's Hospital, which the Medical Research Council had published, he had contrasted the experience in respect of clinically manifest neuro-recurrence in the cases which had been treated there with that of Moore and Kemp who treated rather more intensively but on the alternating plan.

Colonel Harrison thought it reasonable to suppose that, when an early case was treated first with arsenobenzol, the spirochæte tended to settle in the nervous system and got a start of eight weeks in doing so before the mercury or bismuth, with its perhaps more penetrating and certainly more persistent action, was introduced. Colonel Burke had blamed the concurrent method for Wassermann-fastness, but in the speaker's experience the most intractable cases from this point of view had been patients who had received little or no treatment for a number of years. He thought that probably Wassermann-fastness depended mostly on inaccessibility of the parasites, and he believed strongly in the free use of iodides in these cases.

The Intractable Wassermann Reaction.

Dr. T. **Anwyl-Davies** spoke of the influence of sodium thiosulphate on the Wassermann reaction. It had been stated in America that in 10 out of 28 cases whose Wassermann was persistently positive, the reaction became negative after administering that drug.

Dr. **George Riddoch** thought that any explanations put forward for a persistently positive Wassermann must be, in the present state of knowledge, largely theoretical. The view which he favoured was that it was due to the spirochæte being hidden in situations which were inaccessible to the general blood stream. And there was a small group of cases of tabes in which, in spite of a persistently negative Wassermann, the patient went steadily down hill. There seemed to be no evidence in support of the idea of the development of spirochætal immunity to various remedies, not even clinical evidence. Nor was he able to say whether the use of arsenical preparations led to the more frequent development of neuro-syphilis. There was need, he thought, for a tightening up of the experimental criteria in favour of one view in contrast to others. He had used pyrotherapy for cases of Wassermann-fast tabes, with varying results. In a proportion of cases of G.P.I., the Wassermann reaction of both blood and cerebrospinal fluid became negative after a latent period, and if the patient died of some other disease, healed lesions might be found.

Mr. F. **Fowler Ward** agreed that it was possible to give patients too much arsenobenzol. He used N.A.B. and bismuth. If a man, despite a positive Wassermann reaction, seemed to be in good health, why run the risk of making him worse by giving more arsenical injections? A positive Wassermann should not be regarded as a justification for perpetual interference.

Dr. A. **Sharp** said that if a patient had had syphilis ten years ago and his Wassermann was still positive, it was very unlikely that it would ever become negative, whatever was done. To emphasise to the patient the idea that his Wassermann being positive was important tended to produce a phobia about the disease.

Dr. H. M. **Hanschell** said the discussion seemed to show that it did not matter which method was adopted in cases of early syphilis, so long as enough treatment was given. His difficulty in many cases was that he saw them several times, but not again. He was able to say, from his experience, that a concurrent method of treatment did not produce inveterate Wassermann-positive cases. It seemed that the organism of syphilis localised itself in certain parts of the body, where it proved impervious to treatment. If it seemed that a patient's condition could not be altered, it was wise to leave him alone. He had found that the chronic Wassermann-positive cases were those who had acquired syphilis some years before and had never had treatment for it at all, or at best had only had one or two injections of arsenobenzol.

Dr. H. C. **Semon** remarked that if, as was stated, arsenobenzol was excreted within two days of its injection, there must be four days, in these early stages, in which nothing was happening, and in which therefore the spirochæte, as it was unmolested, could get into the central nervous system. This encouraged concurrent administration, with the arsenobenzol of a substance which was not so quickly excreted—namely, bismuth.

Dr. **Margaret Rorke** said that in her work amongst women she saw comparatively few early cases of syphilis. She agreed with Colonel Burke that it was a good thing to administer different preparations of drugs. Otherwise there was bound, later on, to be a Wassermann-fast stage. Sometimes a prolonged positive case would become negative after an interregnum in the treatment, which presumably had given the general resistance of the patient time to rise.

The **President** agreed on the importance of remembering the part played by the tissues in producing a substance which stopped the evil effects of the spirochæte. Using a variety of remedies might cause a continuance of the stimulus which brought this about. The patient must be sufficiently nourished to enable his tissues to respond to these stimuli. He asked whether the practitioner was necessarily on sound lines in feeling that the end of all antisyphilitic treatment was the production of a negative Wassermann reaction.

Colonel **Burke** replied.

Reviews and Notices of Books.

PATHOLOGY OF THE EYE.

By JONAS S. FRIEDENWALD, A.M., M.D., Associate in Pathological Ophthalmology at the Johns Hopkins University, and Pathologist of the Wilmer Ophthalmological Institute. London: Henry Kimpton. 1930. Pp. 346. 21*s.*

THE merit of this work is twofold. The text, being founded on a course of lectures, is in a form that appeals to advanced students of ophthalmology with a minimum of reference to the elements of the subject. Space is thus left for a sound presentation of the various pathological problems presented by the eye, especially in their relation to the problems of general pathology. In addition, there are over 250 excellently clear illustrations in black and white, taken from the pathological collections of the Wilmer Ophthalmological Institute and the Army Medical Museum. These illustrations in themselves constitute a very valuable collection, which even those who possess the larger works on ocular pathology of Sir John Parsons or S. Mayou and Treacher Collins will find useful. As is natural, the most interesting portions of the text are on those subjects to which the author has himself contributed original work. These include observations on subacute panophthalmitis, a term by which, in his opinion, many cases of cyclitis, iritis, and choroiditis arising from septic foci within the eye might properly be known. With regard to the connexion between these cases and septic foci outside the eye, as in the teeth, tonsils, and intestines, his attitude is sceptical. For every organism that comes to the eye, he says, there must be thousands, perhaps millions, that are stopped in the lungs. If the organisms are pathogenic, why do they not produce pneumonia, and if they are not pathogenic why do they cause so much damage to the eye? He proceeds to criticise the theories that have been held to account for this. While not denying the influence of septic foci outside the eye, he evidently considers that the explanation is applied far too promiscuously.

The examination of the eyes of stillborn syphilitic infants has shown in certain cases a diffuse infiltration of the choroid and sometimes of the retina and optic nerve, with wandering cells. In infants that survive, this leads to a widespread interstitial scarring. In some of them the pigment cells are stimulated to migrate into the retina, and these are the cases which in later life are liable to be confused with retinitis pigmentosa.

The author's researches in connexion with glaucoma have led him to disagree with the theory recently propounded by Duke-Elder and others that there is no constant circulation of the intra-ocular fluid, but merely an osmotic interchange between it and the blood, and to support the alternative theory that the aqueous is mainly the product of secretion from the glands of the ciliary body. To oppose the newer theory may appear reactionary, but due weight should certainly be given to Dr. Friedenwald's thesis. In the chapter on senile changes and arterio-sclerosis the author makes an important observation—namely, that in normal eyes the walls of retinal arteries and veins are fused together at the points where these vessels cross one another within a common sheath. Hence the phenomenon of arterio-venous compression so often observed with the ophthalmoscope is due not to increased blood pressure within the artery, but to an actual encroachment of the thickened arterial and venous walls upon the limited space within the enclosing sheath.

It would be easy to continue quoting examples of the interesting matter contained in this book.

PRACTICE OF MEDICINE.

A Text-book of the Practice of Medicine. By Various Authors. Third edition. Edited by FREDERICK W. PRICE, M.D., F.R.S. Edin., Consulting Physician to the Royal Northern Hospital; Physician to the National Hospital for Diseases of the Heart, London. London: Humphrey Milford, Oxford University Press. 1929. Pp. 1871. 36*s.*

THE third edition of this text-book has been revised and brought thoroughly up to date. Some alterations in classification and general arrangement have been made. It is of interest that the article on rickets, which in the last edition was moved from the section on deficiency diseases to that on metabolism, has now returned to its former position. The changes of view and the new discoveries which have occurred during the last three years are noted and described, and this has necessitated much additional material. New articles added include those on lead tetra-ethyl poisoning, carbon monoxide poisoning, basal metabolism, vitamins, megacolon in adults, familial icterus gravis neonatorum, the veronal habit, syphilitic affections of the aorta, heart, and pericardium, and various forms of cardiac irregularity. Much fresh matter in connexion with advances in treatment has also been included. The prophylaxis of syphilis by arsenical preparations, the use of malaria in the treatment of syphilis, the use of plasmochin and plasmoquin in the treatment of malaria, the use of adrenalin, ephedrine, and barium in heart-block, the treatment of ringworm with thallium acetate, and the treatment of diabetes mellitus are a few of the sections which have been added or enlarged. Four further illustrations have been included. The form of the book is unchanged, the print is good, and the index full.

The editor has succeeded in condensing into one volume a remarkable amount of information, and has, moreover, produced a very readable book.

A HISTORY OF SCIENCE.

Its Relations with Philosophy and Religion. By W. CECIL DAMPIER DAMPIER-WHETHAM, M.A., F.R.S. London: Cambridge University Press. 1929. Pp. 514. 18*s.*

THE object of the author of this book is to tell the general story of science, and to present a broad outline of the development of scientific thought, rather than a detailed study of any particular period. After an introductory review, the rest of the book is divided into 10 chapters, of which the first three deal with science in the ancient world, in the Middle Ages, and at the Renaissance period. The Newtonian epoch has a chapter to itself, and so have Nineteenth Century physics and biology respectively. The remaining chapters deal with Nineteenth Century science and philosophic thought, recent developments in biology and anthropology, and the new era in physics; a final chapter is devoted to scientific philosophy and its outlook. To produce a book of such wide scope is a very difficult task—a task that could be undertaken with success only by a man of much general culture, with a well-balanced outlook and a sense of historic perspective as well as an intimate general knowledge of science and of the stages of its development. Dr. Whetham possesses all these qualities and something more besides, for the exposition is excellent and the story equally clear and fascinating, whether we are reading of the contributions to science of Aristotle, or those of Sir Ernest Rutherford.

Considerable space is given to the biological sciences, a section of special interest to medical readers. The story here is developed with sympathy and understanding, and while the advances made by individuals are noted with care, the author keeps his eye all the time on work going on in other branches of science. It is this perspective that makes his book especially valuable. Historians of science too often show a bias in favour of one branch in which they are themselves chiefly interested.

Dr. Whetham has a keen sense of the limitations of physical science which he expresses in his introduction, the last few lines of which may be quoted in full, since they convey well the philosophic outlook of the author. He concludes: "Physical science represents one analytical aspect of reality: it draws a chart which, as experience shows, enables us to predict and sometimes to control the workings of Nature. But the clear insight into the meaning of physical science which is given by modern scientific philosophy shows that by its inherent nature and fundamental definitions it is but an abstraction, and that with all its great and ever-growing power, it can never represent the whole of existence. Science may transcend its own natural sphere and usefully criticise some other modes of contemporary thought and some of the dogmas in which theologians have expressed their beliefs. But to see life steadily and see it whole we need not only science, but ethics, art, and philosophy; we need the apprehension of a sacred mystery, the sense of communion with a Divine Power, that constitute the ultimate basis of religion."

Tissue Culture.

Praktikum der Züchtung von Warmblutgewebe. By Dr. Fritz Demuth, Berlin. Munich: Rudolph Müller and Steinicke. 1929. Pp. 116. M.6.

Dr. Demuth has attempted to produce a simple text-book for those unacquainted with sterile culturing work, rather than a manual for tissue culturists seeking to further their knowledge in the art. He aims at enabling the beginner to master the technique of growing tissue both on coverslips and in flasks, giving descriptions of all the processes involved and illustrating them with some excellent photographs. He lays due emphasis on the difficulties of avoiding bacterial contamination throughout, and on the need for absolute chemical cleanliness. His illustrations of cultures which are faulty in one way or another, because of bad manipulation or incorrect treatment, will be welcomed, but we could have wished for more descriptions and illustrations of cultures under healthy conditions showing good growth. Those unversed in tissue culture will find that the cell growing in cultural media has habits and appearances very different from those of tissue in its normal surroundings in the body; and it is with the appearance of cells, both normal and malignant, in equilibrium with their artificial cultural media, that the worker must become acquainted before he can make any application of the method of tissue culture to the solution of biological problems. Dr. Demuth in his introduction expresses his conviction that tissue culture will open a new door to the domains of biology and medicine, but it must be regarded only as a method and not as a science in itself.

The Chemical Aspects of Immunity.

Second edition. By H. Gideon Wells, Ph.D., M.D., *Professor of Pathology, University of Chicago*; Director of Medical Research, The Otho S. A. Sprague Memorial Institute. New York: The Chemical Catalog Company, Inc. 1929. Pp. 286. $6.00.

This is the second edition of a book which first appeared in 1924. It was reviewed shortly after publication and we then regretted the inclusion of so much literature that the author's critical faculty was left little play. As a work of reference on the chemical aspects of immunity the book has great value, but as a guide to a beginner in this field it lacks coherence. In the second edition the author has considerably enlarged the work, and has included all the recent papers on this vast subject. This has increased the number of opinions recorded; many of them are contradictory, with the result that a general reader must have the greatest difficulty in arriving at the current views on this subject. For example, he would gather, quite incorrectly, from this book, that the Abderhalden reaction is one of extreme importance in immunity, and the same applies to the Meiontadmis reaction. The index is full and accurate, but a separate index of authors would have been appreciated.

Prof. Wells has here provided an elaborate summary of nearly all the papers published on the chemical aspects of immunity. If, in future editions, he would add comments and opinions of his own, the ordinary reader who is perhaps not familiar with the relative merits of the various quoted workers would find the book of considerably more use than it is at present.

Growth and Tropic Movements of Plants.

By J. C. Bose, F.R.S. London: Longmans, Green and Co. 1929. Pp. 447. With 228 figures. 21*s.*

Sir Chunder Bose here publishes another instalment of the results of his devoted labours to investigate the excitability and responses of plants, especially in their analogies with the behaviour of animals. He here describes the effects which he has observed by his extremely delicate recording apparatus of heat, light, gravity, wireless waves, and so on, on the motor responses and growth, and a chapter is devoted to the mechanism of the twining stem. As usual, the author makes no references to the work of other botanists, nor does he relate his own results to what is commonly believed; it is therefore difficult for anyone who is not an expert botanical physiologist to evaluate what he has done. But much of the book is interesting and more of it curious.

Practical Biochemistry.

By A. T. Cameron, M.A., D.Sc. Edin., F.I.C., F.R.C.S., Professor of Biochemistry, Faculty of Medicine, University of Manitoba; Biochemist, Winnipeg General Hospital; and Frank D. White, A.R.T.C., Ph.D. Edin., F.I.C., Assistant *Professor of Biochemistry at the University.* London: J. and A. Churchill. 1930. Pp. 222. 8*s.* 6*d.*

All teachers of biochemistry have their own individual ideas about a practical course, and eventually they nearly all publish a book on the subject. Whilst such a book may be extremely valuable to students working under its author, it does not necessarily follow that it will prove of equal value to the world in general, since it is difficult for anyone to write impersonally on such a subject as a practical course of any branch of science. An author is always apt to emphasise the points that seem to him to be the most important, and his book is more than likely to invite criticism from people who do not agree with the emphasis. Dr. Cameron is primarily a pure chemist, and thus is inclined to regard the chemical work as being the most important part of the course. We find here excellent descriptions of the tests for the elements and the tests for the organic compounds, proteins, fats, carbohydrates, amino-acids, and so forth. The book could only be followed by a student with the help of a series of lectures given at the same time, since the text contains hardly any explanations of the various manipulations and no theoretical descriptions.

The first part of the book deals with the qualitative, and the second with the quantitative and clinical procedures. A good and clear account is given of those tests on blood, urine, and foodstuffs which the authors consider to be the most useful for medical students. They have excluded more complex procedures, such as the electrometric determination of the hydrogen-ion concentration, and also all matter of purely scientific interest which is not essential for the rather circumscribed course of biochemistry which has to be crowded into the medical curriculum. The easier tests, such as the determination of urine constituents, are first described, and after these the analysis of the blood and gastric contents and the determination of basal metabolic rate, so that by the end of the course the student has had experience of nearly all the experiments which are performed on the routine specimens reaching a biochemical laboratory.

The book is much longer and more thorough than those used in most of the English medical schools, particularly the London ones, and the adoption of a course of this kind would be of great educational value.

CARE OF THE SKIN AND HAIR.

Revised edition. By WILLIAM ALLEN PUSEY, M.D., Professor of Dermatology (Emeritus), University of Illinois. London: D. Appleton and Co. 1929. Pp. 182. 5*s*.

IN this little manual one of America's most famous dermatologists has brought together all that the layman and his feminine dependents need to know for the study and care of their complexions. The discouragement of useless fads is the prime object of the book, and it is certain that if all those who contribute towards the 300 millions which, according to another American writer, are spent annually on cosmetics in that country, were to read and mark its contents, there would be a sensible reduction of this gross extravagance. The exposition of the subject is concise—at times epigrammatic. "The only practical way to feed the skin is through the stomach" should explode the most popular of the beauty specialists' many slogans, and every physician will agree that "moles of all things should be left alone by the inexpert."

Three useful diagrams illustrate the microscopic structure of the skin described in the first chapter. The following chapter explains the normal cutaneous functions, and the next two are devoted to the care of the general health in relation to these. Water and bathing, soaps, powders, creams, and physical methods are discussed in an easily comprehensible way in the succeeding sections, and Chapters 8, 9, and 10 contain an elementary consideration of the simpler inflammatory disturbances and common defects of the skin. The final two chapters deal with baldness and other defects of hair growth. The author's theories in explanation of the former can be summarised by attributing it to a "transitional stage in man's evolution." Man no longer uses his hair for protective purposes; he wears a hat, but he cannot save what hair remains by discarding his headgear. It is too late for that. "We are a result of our ancestors, and to save our hair we would have to discard the hats of all our ancestors for scores of generations back." This pessimistic view is unfortunately supported by Jackson and White's statistics, which demonstrate that baldness is hereditary in 30 to 40 per cent. of the cases.

HUMAN CONSTITUTION.

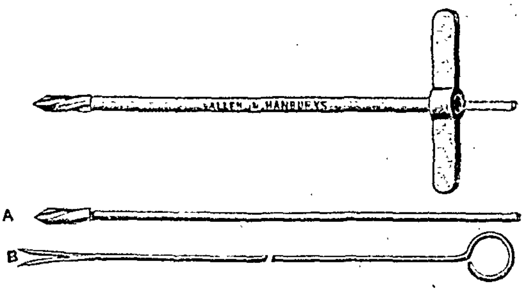
Disease and the Man. By GEORGE DRAPER, M.D. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1930. Pp. 270. 12*s*. 6*d*.

Dr. Draper is spreading his activities too widely. He showed us some time ago that susceptibility to various diseases could be inferred from measurements of the body; that objective anthropometry could identify the constitutions which were particularly liable to develop pernicious anæmia, gastric ulcer, gall-bladder disease, or tuberculosis. In this way he opened up again the old and neglected field of man's constitution as an important factor in preventive medicine. We hoped that he would extend his inquiries along these lines and that other institutions than the New York Presbyterian Hospital would take up the measuring of their patients on the large scale necessary for the confirmation of Dr. Draper's first results. Unfortunately, he has widened the scope of his inquiry, and the present volume is a loosely written collection of chapters dealing largely with a rather nebulous psychology. We wish he had stuck to the dull routine of the callipers and scale; he would have been more convincing and at least as interesting.

New Inventions.

NEW PATELLA DRILL.

THICK rope silk is a very efficient and reliable material for the suture of a fractured patella, but it is not easy to apply the silk with ordinary instruments. To facilitate this operation I have had an instrument made which renders the procedure comparatively simple. The instrument here illustrated consists of a drill and cannula, the feature of which is that the drill is a little larger than the cannula, and so goes through the bone easily, taking the cannula with it. The upper fragment is drilled just above the fracture and the drill (A) pulled out, leaving the cannula in situ. The silk is then pushed through the cannula with the forked probe (B). The lower fragment is then drilled, the drill removed, and the silk pushed through the cannula in the reverse direction, the two ends being tied together. The instrument can be used with the ordinary mechanical drill fitted with a chuck, and works very satisfactorily.

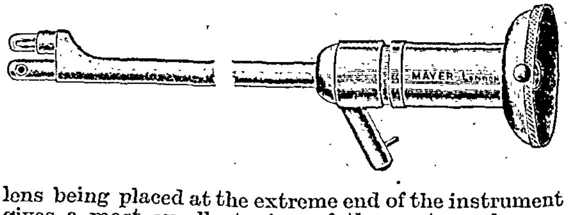


Messrs. Allen and Hanburys, Ltd., Wigmore-street, London, W., are the manufacturers.

HERBERT J. PATERSON, M.Chir. Camb.,
F.R.C.S. Eng.

AN IMPROVED PHARYNGOSCOPE.

THE instrument here illustrated is a modification of Hay's pharyngoscope. It is very much smaller and consequently better borne by a sensitive patient and is especially useful in examining children. The lens being placed at the extreme end of the instrument gives a most excellent view of the post-nasal space and of the larynx. With the light switched on, the pharyngoscope should be introduced in the mouth, pressing lightly on the tongue to get under the arch of the soft palate; the patient should be told to close his mouth and breathe through the nose so as to bring the soft palate forward.



Messrs. Mayer and Phelps, 59–61, New Cavendish-street, London, W., are the makers of the instrument.

E. E. BURNIER, M.D. Lausanne, M.R.C.S. Eng.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 8, 1930.

THE TEACHING OF MIDWIFERY.

Each generation finds it difficult to appreciate the outlook of its predecessors, immediate or remote, and it is peculiarly hard for us to see any excuse for the neglect of the teaching of midwifery, which extends almost into our own time. In his Lloyd Roberts Memorial Lecture, delivered last November, and now reprinted with additions,[1] Dr. Comyns Berkeley has made a serious indictment of the General Medical Council, the examining bodies, the universities and other teaching schools for this neglect of midwifery. He shows how little the obstetric teachers of an earlier generation, even with the help of the Obstetrical Society of London and of other professional organisations, were able to carry with them the existing powers that in their efforts to secure proper clinical training and an obligatory qualifying examination in a subject that bulks so largely in the work of the family practitioner. The mere fact that midwifery had no place at all in the medical curriculum before the Medical Act of 1886 is startling when it is realised that the date is recent enough to allow some of those in practice to-day to have qualified before it came into force. Doubtless the apprenticeship to a general practitioner, a custom with much to be said in its favour, helped to fill up the gaps in the curriculum, but curious anomalies of that time still exist. The General Medical Council has rarely had more than one obstetric teacher among its 40 members, even since training and examination in midwifery was made compulsory and took its place alongside medicine and surgery in the student's curriculum. The Committee of Management of the conjoint examinations of the Colleges has never included a representative of midwifery, although that subject has formed the third division of the final examination for over 40 years. The wonder is that a College of Obstetrics did not arise years ago, instead of but the other day.

The difficulties in providing adequate clinical training in midwifery are considerable, both from the side of the teachers and the medical schools; as Dr. Berkeley points out, the task of convincing their medical and surgical colleagues of their need for more beds and a larger share of the student's time, if he is to be properly equipped for the work of general practice, has hitherto been beyond the power of the obstetricians. The shortage of beds is reflected in the loose way in which candidates are signed up for the examination; the certificates of the training schools are irregular to a degree considered by Dr. Berkeley almost to bring them into the category of forgeries. The figures obtained from the various teaching hospitals (given in an appendix to the paper) show that in London, for instance, the number of cases allotted to medical students averages 14·5, and in some cases 12·7, instead of the minimal statutory 20. In ten London hospitals with medical schools there was a deficiency of 3628 cases for the students they trained, whereas the pupil midwives trained in London had an excess of 7856 cases over the number necessary to provide the 20 demanded by the Central Midwives Board, and but a fraction of these women will practise midwifery. The absurdity of the medical practitioner obtaining less clinical training than the midwife to whose assistance he must go in cases of difficulty is too obvious to call for comment. Dr. Berkeley would increase to 30 the number of cases in which the medical student personally attends delivery, and he would like the General Medical Council to stiffen the required certificates by demanding a type of schedule similar to that adopted by the Central Midwives Board, which includes spaces for the name of the patient, her address, and the date of her delivery, so that it is possible to check the allocation of cases. To facilitate this he would make the poor-law hospitals the chief training ground for midwives and ask the London County Council, for instance, to set aside one of its hospitals of 400–500 beds for their training—and incidentally for a centre of pathological and biochemical research. It is here that Dr. Berkeley's scheme differs fundamentally from that of Mr. Donald Roy, who contributes his reflections to the last issue of the *British Medical Journal* (p. 212). If the medical practitioner and the midwife are to work harmoniously together—and it is in this coöperation that he sees hope of improvement in the maternity service—their training should instil into them the wish to coöperate. Should it be accepted, as he believes, that the good and true tradition of conservative midwifery is to be found at its best in the lying-in hospitals of London and other large centres, progress lies not in excluding the pupil midwife because her keenness filches away from the medical student the bulk of the cases, but in extending the clinical material at these hospitals, if necessary by attaching poor-law beds, and letting the pupil midwife act as monthly nurse for the medical student's cases during the period in her training when she is not herself taking cases. The medical student would then see the midwife's rôle clearly defined. While learning to appreciate and trust the midwife, he would also learn when, where, and how to take over control of a case himself.

The problem of fitting an adequate clinical training in obstetrics into the medical curriculum is one of time as well as of place and personnel. Dr. Berkeley has come to regard six years as its minimum duration, a period now prescribed by most of the great medical teaching centres in the world and even exceeded by some, the longest being nine years in Sweden. In such a programme infant welfare and hygiene are regarded as part of postnatal supervision and complementary to midwifery; the recommendations of our General Medical Council to this effect have remained until now a dead letter. The important place of pædiatrics in the work of the family practitioner also necessitates additional clinical provision for it in the curriculum. Six months at least would be devoted solely to obstetrics and gynæcology, of which four should be allotted to midwifery with its ancillary services of prenatal and postnatal supervision and infant welfare, and two to gynæcology—the common minor ailments rather than the details of operative technique. Of this time two months, preferably more, should be spent in residence at a lying-in hospital or maternity department with at least 50 beds. To these and the many other constructive suggestions made by the Lloyd Roberts lecturer all interested in medical education should pay heed.

ACUTE OTITIS MEDIA.

ACUTE inflammation of the middle-ear cavity, common enough at all times, is especially prevalent at this time of year, and it is therefore appropriate to pass in brief review the salient features of this important affection. In the overwhelming majority of cases the infecting organisms gain access to the middle-ear cleft from the nasopharynx along the Eustachian tube. The inflammation is not confined to the cavity of the tympanum, but involves the whole of the tract of the middle ear; for the Eustachian tube itself, the tympanum, the antrum, and the mastoid cells are all implicated.

The infection may be caused by a great variety of organisms, but in any individual case it is usually due to one variety only—that is, an organism is obtained in pure culture from the middle ear. When perforation of the membrana tympani has taken place, secondary infection with the organisms present in the meatus can readily occur; this is believed to be the principal cause of failure of resolution and consequent chronicity, and its prevention is one of the important aims of treatment. In some epidemics of the acute specific fevers, notably scarlet fever, measles, and influenza, the infection is of extraordinary virulence, and rapidly involves the bony walls of the cavities, and produces by extension the well-known and dreaded intracranial complications. But in the great majority of cases the virulence is far less severe, the bone is not seriously affected, and the inflammation is almost confined to the mucous lining of the aural cavities. As the entire cleft of the middle ear is involved in the inflammation, it follows that in any case of acute otitis with earache, tenderness is likely to be present over the mastoid, either over the antrum or the mastoid tip, or in both situations; but at this stage such tenderness does not imply that surgical opening of the mastoid cavity is indicated. The key to the cure of inflammation of these cavities, as of most other inflammatory diseases, is free and unobstructed drainage. In the earliest stage the fluid secreted can drain down the Eustachian tube, and many cases of mild inflammation of the middle ear do drain and get well in this way. But in severer cases the tube is obstructed by swelling of its mucous lining, perforation of the membrana tympani occurs, and drainage by this route with subsequent healing results. Sometimes, again, there may be a block at the aditus, or at the neck of a mastoid cell, or group of cells, with the result that the mastoid becomes surgically involved.

These facts should form the basis of the treatment of all inflammations of the middle ear. In the mildest forms, with little or no pain, but with a feeling of fullness and some impairment of hearing, gentle inflation with the Eustachian catheter will often re-establish the patency of the tube and hasten recovery. When earache is present the prompt use of an antiseptic in the meatus is of value to sterilise the canal and prevent secondary infection should the membrane perforate or have to be incised; a 5 per cent. solution of phenol in glycerin is frequently employed and has the additional advantage of acting as a local sedative. But when pain is severe and accompanied by fever, a timely incision of the drum membrane is the best of all therapeutic measures, and in a very large proportion of cases is speedily followed by cessation of the earache and recovery from the inflammation; there is no need to wait for bulging of the drum. This little operation is not difficult to perform, and is much more often postponed too long than done too soon, but a general anæsthetic should be given, for it causes intense pain in an acutely inflamed ear. If symptoms persist for more than a few days after free drainage of the tympanum has been established, the probable cause is obstruction of drainage at the aditus or in the mastoid cells, and a mastoid operation is desirable. In a few cases a profuse discharge continues in the absence of other symptoms; if this remains without abatement over some three or four weeks, it is probably due to partial obstruction in the mastoid, and also calls for operation in order to avoid chronic suppuration.

ASPIRATION OF DIPHTHERITIC MEMBRANE.

IT is related that on one famous occasion Stalky fulfilled his threat to get even with the Head for "a lickin' from King, 500 lines, *and* a gating," and the method of his revenge was the publication of the Head's gallantry in applying the aspiration method to the diphtheritic membrane of Stettson major, a mere day boy. Certain workers in America have been attempting to perfect a routine by which aspiration technique can be applied to diphtheria in the larynx as well as in the fauces, and without the element of personal risk which provided Stalky with his triumph. The procedure, which was initiated in 1922, is associated with the name of Dr. HARDMAN, now of the Ontario State Public Health Service, and has been gradually developed. For the last four or five years it has been used regularly in several American hospitals and references to it have appeared from time to time in the Weekly Bulletin of the Health Department of the City of New York. No paper, however, has yet appeared giving full details of the technique and an adequate statistical estimation of its value. The chief medical officer of the Metropolitan Asylums Board therefore decided to draw the attention of his Board to the desirability of obtaining first-hand information on the value of the method, and Dr. ALEXANDER JOE, medical superintendent of the North-Western Hospital, was sent out to New York to investigate it on behalf of the Board. His report, which has been published,[1] was the subject of discussion at a meeting of the Fever Hospital Medical Service Group of the Society of Medical Officers of Health last week.

The aspiration method employed at the Willard Parker Hospital, New York City, was described in detail in our last week's issue (p. 257). The apparatus required is simple and inexpensive and consists of a laryngoscope; a portable suction apparatus, run off the hospital current; a number of sterile laryngeal swabs fixed to the swab-stick by collodion and held in artery forceps; a tongue depressor; and the special brass suction tubes, which can be made for a few shillings. The American authorities recommend that none of the apparatus should be plated because of the risk of roughening or scaling of the plating after much cleaning. The patient is wrapped in a sheet and held by a nurse, while another nurse steadies the head in such a way that it hangs backwards over the end of the table with the medial plane at right-angles to the table. The laryngoscope is introduced so that it rests on the upper teeth in the mid-line, bearing on the roof of the epiglottis. After a thorough inspection of the larynx a swab is passed for direct culture, and the aspirating tube is then used once or twice as required. The operation lasts a few moments only, and—provided the operator is reasonably skilled—causes the patient no more than a little discomfort. At the Willard Parker Hospital no anæsthetic was given for its performance. It is particularly useful at the intermediate stage of membrane formation, the stage at which the patient usually enters hospital. The membrane is then readily detachable and there is little œdema and no hæmorrhage.

---

[1] Metropolitan Asylums Board, Infectious Hospitals Department. Report on the Aspiration Method of Treating Laryngeal Diphtheria. By Alexander Joe, M.D., D.P.H. Office of the Board: Victoria Embankment, E.C.

The statistics available are unfortunately inadequate to provide any reasonable indication of the value of this method, but it is always true that the personal impressions of good clinicians are worth more than many volumes of figures and Dr. Joe found that the physicians in New York and Boston who had followed the progress of the work were unanimously in its favour. It is no derogation of a new technique to say that the personal element enters very considerably into its success, and Dr. Joe found that the technique is not difficult and should be equally successful in the hands of anyone with the dexterity to perform a direct laryngoscopy. It seems to be safe, and the only mishap on record is the loss of a milk tooth. Although in America it has always been used as a substitute for or accessory to intubation, Dr. Joe sees no reason why it should not be equally valuable in cases where tracheotomy is the operation of choice; indeed, aspiration through the tracheotomy tube might turn an apparent failure into a success. The introduction of diphtheria antitoxin marked such a tremendous advance in the campaign against the toxic aspect of diphtheria that the obstructive aspect is apt to be forgotten by those who do not constantly have to deal with these distressing cases. The aspiration technique, if it proves as safe, simple, and inexpensive as Dr. Joe suggests, will certainly deserve most serious consideration by all who are concerned with the treatment of croup.

◆

MENTAL PATIENTS AND THE JUSTICE'S ORDER.

In the Mental Treatment Bill as it comes before the House of Commons no justice's order is required for temporary treatment. It is not easy for the medical profession to form an unbiased opinion on the necessity for the justice's order before the reception of mental patients in hospitals or into private care. The welfare of the patient is the doctor's first thought, and when he is satisfied that immediate treatment is necessary he chafes at the delay that the application to a justice involves, and he sympathises with the unwillingness of the friends to make the application. When this means a revision of the case he is impatient, and resents the interference of a layman in what he considers a purely medical matter. Familiar with the procedure in infectious disease he sees no reason why mental illness should not be treated in like manner. Conscious of singleness of purpose in regard to the welfare of his patient, he is convinced that the medical profession can be trusted to discharge its duty properly. On the other hand, the sacredness of liberty is so important in the minds of those with whom the freedom of the subject is a religion, that they feel that, even if treatment be delayed in some cases, even if now and then patients commit suicide when the justice declines to sign the order, and even if the procedure is painful to relatives, yet the welfare of the community justifies the present procedure. If they are told that the recent Royal Commission found no single person improperly detained, they will reply that this is because the present procedure is successful.

In a recent pamphlet[1] by Dr. J. R. Lord the whole question of the procedure for the admission of persons suffering for mental illness is discussed. Dr. Lord would discard the justice's order and in its place substitute the approval of "a panel of approved citizens," appointed by the local authority. There would be no formal order, but the approved citizens would merely endorse the medical certificate. It is doubtful whether this procedure would satisfy the liberty-of-the-subject enthusiast, whether it would be more acceptable to the relatives of patients, or whether in practice the "approved citizen" would be in any way preferable to the magistrate. But while saying this we are grateful to Dr. Lord for directing attention to a subject that deserves serious study. Everyone with experience knows that the justice's order is really little or no safeguard against improper detention. Some justices are complaisant, taking little trouble when the parties concerned are known to them; some are so oppressed with the responsibility of signing orders that grievous delay in treatment occurs; some find the duty thrust upon them by the State so unwelcome that they rely entirely on the clerk. Incidentally the refusal of a justice to recognise a case of high-grade deficiency may and does lead to the procreation of illegitimate children. The position is often most painful when a patient under care exercises his right to see a justice after his admission. A medical officer of long experience tells us he cannot recall a single case in which this did any good, unless it be called doing good to be in a position to tell the patient afterwards, "Well you had your chance and saw the justice." All this is wrong in principle; it emphasises the detention, and ignores the medical aspect of the case.

The value of the intervention of the justice should be examined afresh by a select committee or some other impartial body. It may not be remembered that Lord Shaftesbury, who probably more than anyone in his day contributed to the reform of our mental institution, who was responsible for the passing of the 1845 Acts (often called the Magna Charta of the insane), and who was one of the first lunacy commissioners, protested to the end against the introduction of the justice, and when overridden by the Act resigned his commission. Now nearly 40 years have elapsed and the question arises whether, after all, Lord Shaftesbury may not have been right. If he was it follows that the procedure which seems now to be embedded in English law is really unnecessary and is retarding the treatment of mental disease. We are glad the Ministry takes the view that a justice's order for temporary treatment would defeat its own object.

Freemasons Hospital and Nursing Home.—During the past year the pressure upon accommodation was so great that the staff had to be provided for in five separate buildings. The "case days" increased from 14,772 to 15,872. Large extensions are to be made at a cost of £250,000, of which £100,000 is in hand; the land has already been paid for. There were 610 in-patients during the year, 32 of whom came from over-sea.

Hospitals and Motor Accidents.—Motor accidents last year cost Altrincham General Hospital £1050. Many of the injuries were sufficiently serious to necessitate prolonged stays in the hospital. In the three months ending with October last the motor accident cases treated at the Royal United Hospital, Bath, numbered 21 in-patients and 26 out-patients. The in-patients remained for a total of 235 days at a cost of £91, of which £1 7*s.* 6*d.* was repaid.

Annotations.

"Ne quid nimis."

THE INTERNATIONAL CONGRESS OF MENTAL HYGIENE.

THE National Council for Mental Hygiene is acting in Great Britain as a liaison body in regard to this Congress—the first of its kind—which is being held in Washington from May 5th to May 10th. The Study Tours Sub-Committee of the Royal Medico-Psychological Association have now organised a study tour in the United States in connexion with the Congress, and prompt applications are invited from those who propose to attend the functions. A United States correspondent has already described the activities on the other side of the Atlantic (THE LANCET, Feb. 1st, p. 260), from which the intention to make the occasion an important one can be gathered. Attendance at Washington is not limited to members of particular organisations or to official delegates, but affiliation to the Congress is open to all interested in mental hygiene, while members of the Royal Medico-Psychological Association will be able to participate in the Tour projected to take place before the Congress. Those doing so will visit, as a party, representative American institutions, and obtain an opportunity of familiarising themselves with the practical as well as the scientific aspects of American psychiatry under advantageous conditions, economical and otherwise. Copies of the programme of the Congress and Tour, and forms of application, can be obtained from the Secretary of the National Council for Mental Hygiene, 78, Chandos House, Palmer-street, London, S.W. It will be a great convenience if those who wish to attend the Congress would send their names and addresses at once to Dr. J. R. Lord, Horton House, Epsom, while those who are members of the Royal Medico-Psychological Association should communicate with Dr. A. Edward Evans, 3, Rotherwick-court, Golders Green, N.W., who is acting as hon. secretary of the Study Tours Sub-Committee. Decisions to join the party should be made at once, as reservations for berths and hotel accommodation are limited. The travel arrangements are in the hands of Messrs. Thomas Cook and Son, Ltd., and intending delegates will receive every assistance by communicating with the head office of that firm, Berkeley-street, London, W.

AN UNUSUAL EPIDEMIC OF DIPHTHERIA.

THE January number of the *Journal of Hygiene* contains an instructive account of a diphtheria outbreak in New Zealand. It appears that in a certain small township the attack rate for diphtheria was, in 1926, equivalent to about 30 years of the London endemic. This high morbidity was attributed to the "unsalted" condition of the community. The cases occurred in two distinct groups, and all the circumstances suggested that the majority of the earlier set of cases contracted the disease by means of droplet infection in the local school. The later group were infected by milk, and the incidence fell chiefly on pre-school children and adults, presumably because the school age group had been partially immunised by the preceding air-borne outbreak. The epidemic afforded an opportunity of making some exceptionally interesting observations on Schick immunity and the rate of artificial immunisation. At the time of the first outbreak samples of the children were Schick tested, and those who reacted were given a course of toxin-antitoxin mixture. Owing to the inadvertent use of a deteriorated Schick toxin, many children, who would have reacted to a fully potent toxin, were falsely recorded as immune, and were not given prophylactic inoculations. When the second outbreak materialised there were two groups of children—those who had had prophylactic inoculation and those who had not—and it was noted that the incidence of diphtheria among the inoculated group was not significantly different from that of the total community. This disappointing result was, however, explained when a second series of Schick tests, six months after the first, showed that 72 per cent. of the presumably protected children had failed to acquire active immunity. The failure of the prophylactic course to induce immunity in the majority of those who received it is attributed to the lack of diphtheria experience in rural as compared to urban districts; it was found that in the orphanages of Dunedin city 100 per cent. of the Schick susceptible children acquired immunity within four months, with the same prophylactic course that failed so conspicuously in the unsalted rural district. This observation points the practical lesson that the more unseasoned a community, or the higher the original percentage of susceptible Schick reactors it contains, the more intensive must be the prophylactic course if it is to be successful in inducing active immunity against diphtheria. Because of these and other lessons this New Zealand epidemic deserves the careful consideration of epidemiologists.

A DECLARATION OF FORMULAS.

THE technicalities of the Medicine Stamp Acts and of their administration have rendered possible a new development, the implications of which are of wide interest, in the large-scale manufacture of proprietary medicines. There is reason to suppose that the first English nostrums of which we have any record were not secret remedies. Thus we find George Wilson, the chemist whose aqua mellis was supplied to James II., advertising proprietary and other remedies in 1686 with the invitation: "And at all times a Free and Welcom access to see any of those Medecines you shall have of me, prepared from the beginning to the compleating of the same." And there is in the Public Record Office a letter from Dr. John De la Bere, of Christ Church, Oxford, dated March 23, 1596/97, containing the passage: "Those Specifica medicamenta, wh were promysed to be p'pared for me, by your London Chymyst, I could never obtayne. Wherefore . . . I am forced now to bylde a Laboratorie or Styllhouse of myne owne . . . ." Secrecy was at first, not improbably, a weapon against unscrupulous competition; but secrecy had the manifest drawback of becoming, in some circumstances, indistinguishable from quackery. The first Medicine Stamp Act, passed in 1783, taxed secrecy except when secret remedies were sold by persons who had served "a regular apprenticeship to a surgeon, apothecary, druggist, or chymist." The principal Act now in force, that of 1812, does not perpetuate this comprehensive exemption, but lays on vendors the onus of showing a remedy to be "known, admitted, and approved" as the condition of sale unstamped. Reduced to its simplest terms, the relevant clause provides that such remedies shall not be the outcome of "any occult secret or art," shall not be associated with an exclusive right of manufacture, shall not be patented under the Great Seal, and shall not be held out as nostrums or as specifics. In practice, the Board of Customs and Excise, the administrative authority, requires a declaration of formula either on the label of each unstamped medicine or in an approved book of reference. The remaining obstacle, that of trade-mark rights, is surmounted by registering a trade mark for a series of articles and not for a single medicine. Such remedies can be sold unstamped by chemists (including limited companies carrying on business under Section 3 (4) of the Poisons and Pharmacy Act, 1908) and by the small class of other persons who have served a "regular" apprenticeship. Vendors not so qualified must take out a patent medicine licence. Until the last few weeks this exemption has only been used on any considerable scale in respect of medicines the composition of which was easily deducible. Now, however, manufacturers of proprietary medicines extensively sold have begun to avail themselves of the exemption in one of the two permitted ways. The departure is of interest in that such medicines are no longer secret remedies—though a casuist might argue that they remain secret when sold stamped. As a matter of fact, it has long been the rule in various Continental countries that all imported medicines must bear a declaration of formula; and in this way analysts and other people interested have easily come to know the composition of remedies that in this country have been regarded as secret. Some years ago we printed[1] a number of formulas of British and American specialties as disclosed to the Italian customs authorities by the makers themselves. A long way has been travelled from the state of things familiar in the early years of the eighteenth century, when arcana were advertised as obtainable "at the author's house." The proprietor or part-proprietor of the modern "nationally" advertised medicine may well be a man of high education who in his heart despises secrecy and is quite willing to let the world know his formula, confident that his long experience in turning out a particular compound will ensure its predominance in a more open market. Obviously the disclosure of the formula should in every case be complete; a mere list of ingredients will not suffice. It remains to be seen to what extent the principal manufacturers of proprietary medicines will decide on disclosure, and what the effect will be on the revenue from medicine stamps, which has averaged for the past ten years about £1,300,000 annually.

UNITED STATES ARMY MEDICAL EQUIPMENT.

IF nations were consistent in their preparations for war they would observe just as much secrecy over advances in military medicine and equipment as they do over a new gun or submarine. But fortunately for our faith in humanity they do not carry these matters to their logical conclusion and any advance in the technique of treating battle casualties is published to the world at large. The Wellcome Prize for research in this field has been won for 1929 by Major J. P. Fletcher, of the United States Army Medical Corps, for his report on the Army Medical Department's Equipment Laboratory, and the work done there since the war.[2] The scope of this work has been very varied, and some 37 different articles of equipment have been considered, the most important among which were first-aid dressings; individual equipment for medical, dental, and veterinary officers, N.C.O.'s, and privates; standard medical field containers; a metal litter for airplane and trench use; types of ambulance bodies; a collapsible two-wheeled litter cart and heaters, lighting sets and laboratory equipments for field hospitals. Major Fletcher says that whenever a proposed model is considered certain factors have to be borne in mind. These are: possibility of production in quantity; availability of material in time of war; replacement of breakage; cost as compared with utility and time, weight or space saved; simplicity and "fool proofness"; applicability of the device to additional uses. After exhaustive tests by the laboratory and in the field, the model has to be passed by the Medical Department Board, and any other arms of the service which may be interested in it. Under such searching conditions, about 70 per cent. of models are rejected. As regards first-aid dressings there were five of these in use in the U.S. Army at the end of the war. These have been reduced to two; a small, which is a five by seven inch gauze-covered cotton pad attached to a four-tailed bandage, and a large, which is approximately 12 inches square, but otherwise identical. The application of wheels to a stretcher is obviously desirable, but the two-litter carrier evolved during the war for traction by men or behind an ambulance proved unsatisfactory. The laboratory have designed a two-wheeled cart which can be clamped on to any standard army litter. This cart weighs 70 pounds, and is mounted on small rubber tyred "buggy" wheels which can be folded with the wheels parallel to the axle, to be hung on the back of a vehicle. It is claimed that tests have shown that evacuation of wounded can be greatly speeded up by its use. A considerable advance has been made in ambulance design. During the war two types were found to be required, a light Ford type for front line work, and a larger type for use in convoys. The war-time three-litter Ford type has been developed into a four-litter body on a passenger car chassis, the whole ambulance so light that it can be lifted bodily by 14 men. The old four-litter heavy type mounted on a standard one-ton truck chassis has been changed to a six-litter body weighing less than the original pattern, and with the driver's seat completely enclosed in glass. This body will carry six lying cases or twelve sitting cases and one lying case, or six sitting cases and three lying cases—in other words, there is an all-round increased carrying capacity of 50 per cent.

HÆMATURIA CAUSED BY INHALING TURPENTINE.

A RECENT outbreak of hæmaturia on one of H.M. ships appears to have been due to inhalation of turpentine vapour by seamen engaged in painting in enclosed spaces. Surgeon-Commander H. Wilks[1] reports that symptoms arose after one or two days' work, seven men reporting themselves sick within a week. The patients complained of scalding pain at the end of micturition, and, in some cases, of frequency; the urine contained blood and had the violet odour associated with turpentine poisoning. The hæmaturia disappeared spontaneously and rapidly in hospital, and showed no signs of recurrence on return of the patients to work. The turpentine used was analysed and was reported by the Government analyst to be good and normal. To prevent further cases, the parties of seamen engaged in painting were cut down and distributed at greater distances from each other, and orders were given for removal of paint from hands and faces before eating. No more cases arose after the parties had been thinned out. There is a possibility that the turpentine used was insufficiently mixed with the flatting, for the seaman responsible for this task was hard put to it to keep pace with the demands of the painters. The vapour of the turpentine was therefore more quickly released than it was removed by the ventilation system.

THE BARGEE'S CHILD.

WHILE the slums of London continue to advertise on a large scale the effect of overcrowding on child life, it seems curious to bewail the lot of the few children living on barges. Lieut.-Colonel Fremantle, during the debate on the second reading of the Canal Boats Bill on Jan. 31st, estimated the number of these children at 3000, and said that of these only 1000 were receiving no education. Further, though the sleeping quarters on canal boats are confined, ill-ventilated, and overcrowded, and the sanitary arrangements are usually primitive, there is no evidence of a lower standard of health among barge-dwellers than among town- or country-dwellers of the same class. In point of fact, the bargee lives less in the cramped cabin than the average cottager lives in his house; it is difficult to persuade a normal child to stay indoors; it must be almost impossible to prevail on him to stay in the cabin of a barge. But while the London slum child plays in the street, the child of the barge plays in fresh air on the deck or banks. Eight hours in overcrowded sleeping quarters have thus to be set against the remainder of the day, which is spent in the

open air. Certainly, should the child fall ill the conditions are highly unsuitable both for nursing and for adequate medical care, and early removal to hospital is the only remedy. That the children take part in the work of the barge is not surprising; but there is no reason to assume that the bargee, who (apart from a notable but possibly mythical vocabulary) does not differ from other men, is likely to make his children wretched by overworking them. The difficulty of educating these children certainly calls for thought. A canal-boat school, as Mr. Harry Gosling explained when moving the second reading of the Bill, has all the disadvantages of a canal boat and few of the advantages of a school. The children attending would be educated among themselves with no possibility of mixing with other children, and the damp quarters, absence of playgrounds, and of sanitary arrangements make such a school most undesirable. Even so, it seems a drastic measure to try to combat these disadvantages by making it illegal for children to be on such boats. If this is done the mother will be forced to set up house on shore with the children, and family life will at once come to an end. Though it has been suggested that the absence of women from the boats would entail addition to the crews and hence increase in cost of transport, Mr. Gosling is of the opinion that reconstruction of canal boats should prevent this. He went on to describe the difficulties of childbirth on a canal boat, with inadequate preparations and in the presence of most of the family. Granted that this is extremely undesirable it occurs with great frequency in any slum district, and is not peculiar to barge life. The problem of overcrowding is fundamental, and not to be cured by removing children from barges. Canal boats used for the removal of house refuse, however, are certainly an unsuitable environment for the upbringing of children, and the public should be able to learn what proportion of canal boats are used for this purpose and whether the same boats perform this function continuously or intermittently. That children do live on such barges at present is proved by the reports of the Ministry of Health inspectors; the report of the Public Cleansing Committee also discusses the matter, and recommendations were made by the inspectors that children should not be allowed to live on refuse barges. While no medical man would fail to support such a suggestion, many will hesitate to agree to the wider application implying the de-barging of all these children.

PSITTACOSIS IN GERMANY.

FURTHER information is now available about some of the German cases of psittacosis to which our Berlin correspondent referred on Jan. 25th. Writing from Hamburg, Prof. C. Hegler[1] describes two small outbreaks, one of which involved three members of a family which traded in animals and the other some of the staff and patients of the St. Georg Hospital. The clinical picture in all the nine cases was, he says, surprisingly uniform, and included pneumonia. The bacteriological findings were negative, although a special search was made for *Bacillus psittacosis*, and Hegler thinks that the disease may be due to a filtrable virus acting, perhaps, in combination with bacilli such as pneumococci and streptococci which happen to be present. The isolation of such a virus was reported in our last issue by Bedson, Western, and Simpson. Prof. H. Embden and Prof. G. Adamy[2] describe 14 cases observed in the general hospital at Barmbeck. All the patients manifested symptoms similar to those of the English cases, and the bacteriological findings were all negative. Dr. G. Elkeles[3] contributes an account of an outbreak last November in a Berlin household, a member of which had brought back from the Upper Amazon four birds, three of which were very ill. With one exception, all those living in the house fell sick; two died and three narrowly escaped with their lives. A friend to whom one of the sick birds was given also fell ill, but the family which received the sound bird showed no signs of illness. All the patients suffered from severe cerebral symptoms and circulatory disturbance, together with an atypical form of pneumonia without sputum. In another small outbreak the infection attacked six persons who had come into contact with a parrot. Cultures from the organs of the dead patients gave no data of ætiological significance, and investigation on the dead birds also produced no result. Elkeles does not believe that *B. psittacosis* has anything to do with the disease.

THE CONTROL OF BOVINE TUBERCULOSIS.

Dr. George Hilton[1] gives a valuable account of what has been done and is being attempted in Canada to control bovine tuberculosis. The first step in 1896 was the offer of free testing of herds with tuberculin, an offer which met with little response. In 1903 an Act was passed making it compulsory to place an identification mark (a punched T) upon all reacting cattle. No opposition is recorded, a matter of interest since such action is a very debatable and controversial matter in this country. The supervised herd plan was adopted in 1905, but made little progress. In 1914 municipalities were required to limit their milk-supply to officially tested herds, a procedure which broke down in practice owing to the refusal of many dairymen to submit to the testing of their herds, while the complaisant could not provide an adequate supply of milk. This was got over by allowing untested herds to supply if the milk was pasteurised. These measures, if their actual results were small, were certainly instructive and thus enabled the Federal Department of Agriculture to introduce the accredited herd plan in 1919. Under this plan, much used in the United States, the aim is to eradicate tuberculosis in individual herds and then maintain them free from this disease. The testing and retesting of cattle is done free of charge, and compensation is paid for slaughtered reactors upon a fixed scale. On March 31st, 1929, there were approximately 4000 fully accredited herds apart from 2000 herds in process of becoming accredited. Ancillary to this, the restricted area plan was adopted in 1922. Provided at least two-thirds of the cattle owners in any specified area sign a special petition, and this is approved by the government of the province concerned, the plan is put into operation. The object of the plan is to test all herds in a defined area as expeditiously as possible, with a view to locating the infected herds, and steps are then taken to eradicate tuberculosis in these herds, compensation being paid for slaughtered reacting animals. Compensation is only given after satisfactory disinfection of the premises. Retesting is, of course, necessary, and steps are taken to prevent the introduction of infected animals. The area plan is considered the more economical, and it promotes better housing and other sanitary conditions for the cattle. When Hilton's paper was written there were eight restricted areas with approximately 700,000 cattle. In general, these two plans have made great progress and about one-ninth of all the cattle in the Dominion have been tested at least once, while over 114,000 reactors have been slaughtered. There is an increasing demand for tubercle-free cattle and milk.

It may be pointed out that the above schemes are only practicable in areas with a low incidence of bovine tuberculosis. Hilton does not give the average incidence in Canada, merely remarking that it is comparatively low, but the procedures are nearly identical with those employed in the United States where the percentage varies from only 3 to 5 per cent. In England our rather imperfect data suggest that it is not less than 40 per cent. and in many areas considerably more; so that these American methods are really impracticable here. Notwithstanding this fundamental difference these drastic eradication methods are not without their supporters in this country. Quite recently the West of Scotland Division of the National Veterinary Medical Association has issued a pamphlet entitled "Scheme for the Eradication of Bovine Tuberculosis," which while differing in details from the American model is, nevertheless, based on the same principles.

[1] Jour. of Dairy Research, 1929, i., 58.

It is of interest to note that Dr. Hilton's article appears in the first number of a new periodical, the *Journal of Dairy Research*, which is financially supported by the Empire Marketing Board. Lord Passfield, in a foreword, states that the journal is designed to assist dairy research workers in every part of the Empire, and is planned to include in each issue three classes of material—namely, a monograph by a leading authority on some broad question of dairy research work, detailed papers of scientific interest, and reviews and records of current scientific contributions to dairy research. There is ample room for such a publication, and if later numbers are up to the standard of the first issue it should find a large and appreciative circle of readers. The editor is Dr. R. Stenhouse Williams, of Reading, whose name will be familiar to many of our readers in connexion with his work as Director of the National Institute for Research in Dairying.

TREPANS AND TREPHINES.

FEW instruments employed in surgery at the present time have a more interesting and ancient history than the trepan. Its use dates back at least 2300 years, when Hippocrates first described the various instruments employed in his time in the operation of trepanning. Even long before this period there is evidence that prehistoric man practised the operation by scraping away the bone with a piece of sharp flint or obsidian as the bushmen of Australia and the natives of New Britain and New Ireland do at the present time. In the New World the Incas of Peru, from a period of antiquity, employed a flint with a serrated edge to remove the fractured bone, as shown in many skulls that have been excavated. The ancient Greeks used three kinds of instruments for trepanning—viz., the terebra or borer, the terebra serrata or circular saw, and the perforator, which was operated with a bow drill. The first, which had a spear-shaped point, was employed when the piece of bone to be removed was larger than could be covered by the circular terebra serrata, and was operated by means of a thong twisted round the centre or attached to a cross-beam. It was used for boring holes around the piece to be removed, and when this was done the lenticular was introduced to break through the interspaces between each perforation, and the roundel of bone then removed. The terebra serrata was a conical piece of metal with a serrated edge, shaped somewhat like a thimble, with a straight shaft rising from the top, and was operated by rapidly rolling the shaft between the palms of the hands. In this instrument we have the origin of the crown saw which the Romans adopted for their modiolus. They also employed the terebra, which they operated with a bow-drill, using a terminal with a sharp point which suddenly became broader, as described by Celsus. In the twelfth century Albucasis described an instrument terminating in a spear-shaped head called "incisoria," and a borer with a sharp point, both of which were employed in his time for trepanning; while in the fourteenth century Lanfranc alludes to a borer with a spear-shaped point called a "trepanon" for making a ring of perforations. In an interesting manuscript of the same period by John Wryghtson, an English surgeon, there is a drawing of an instrument similar in shape to the Roman modiolus with a circular saw and centre-pin, fixed to a straight handle, which was evidently operated by rolling between the palms of the hands. In the fifteenth century Bruynswyke described and figured "trepanes" terminating with a long gimlet-like screw, "to make small holes in the skull." Andrea della Croce, the Italian surgeon, in his work "Chirurgie" printed in 1573 devotes considerable space to the operation of trepanning, and describes several instruments with a brace and drill-stock, to which a circular saw or perforator could be fixed with a screw as occasion required, and the same type of instrument was used and described by Ambroise Paré.

The first mechanical trepan was described by Matthia Narvatio of Antwerp in 1575; this consisted of a horizontal beam with a cog-wheel in the centre, turned with a handle, that actuated the saws or borers, which were fixed on a straight bar with a screw. To Fabricius Aquapendente (1537–1619) is attributed the invention of the trephine, though Woodall in 1639 alludes to the trephine as "an implement of my owne composing," it was figured by Fabricius before his time. According to Savigny, "The name trephine is so-called from the triangular form it acquires by the horizontal position of its handle, in contradistinction to the trepan, in which the head or crown is affixed to a frame or brace, similar to and used in the manner of the carpenter's wimble." To Fabricius is also attributed the introduction of the trepan saw with shoulders, which prevented the instrument sinking down into the membranes of the brain; although Ambroise Paré figures a brace or drill-stock with a binding screw to fix the saw, the drum of which was straight and smooth, with a shoulder of a similar kind. Paré described "trepanes" as "round saws for cutting out a circular piece of bone with a sharp-pointed nail in the centre projecting beyond the teeth." He also figures a trephine which he says, "is most in use and the fittest, set forth by Dr. Crooke." In the seventeenth century Scultetus describes a trepan operated with a drill-stock which he calls "the handle," and also mentions a trephine with a transverse handle to which circular, conical saws could be fixed.

The eighteenth century marks a new era in the history of the instrument, during which the trephine gradually replaced the trepan worked by means of a brace or wimble. In 1739 Sharp introduced his trephine with a wide transverse handle of steel, the extremities of which were roughened so that they could be used as elevators. He claimed to be the first to use a trephine with a cylindrical in place of a conical, crown saw, with a key to remove the centre pin. Heister in 1743 says, "the moderns have a method of fastening the crown on the trepan otherwise than by screwing, but this is my way." He upheld the use of the screw and the saw with a conical crown. He also describes an exfoliative trepan, the handle and saw of which were fashioned from one piece of steel. In 1779 Petit introduced his perforator with a steel drill head, smooth and bevelled for drill edges, but the head was shorter than Sharp's. The type of instrument used at the close of the century is thus described by Savigny in 1798. "It had a cylindrical saw with a smooth drum, the barrel being inserted into the handle direct. It had fine teeth without gaps, and the pin ran into a slot in the barrel regulated by a binding screw and plate." The peculiar formation of the teeth (exactly perpendicular) was claimed to be an important advantage to the operator. "At this time," remarks Savigny, "the trepan used with a brace or wimble is now wholly laid aside in this country." In 1801 Benjamin Bell introduced his trephine with a wooden cross-bar, into the middle of which was screwed a steel key-barrel with a spring grip made to grasp a slot in the key-end of the trephine saw. The chief improvement was in the saw, which had a cylindrical smooth drum, with long straight teeth arranged in three series of nine, three gaps being thus left to let out bone dust, the forerunners of the windows in modern instruments. The prismatic was controlled by a thumb or binding screw and plate, which worked in a slot on the side of the barrel. Rudtorffer introduced a further improvement in 1817, by adding a screw button in the shaft by means of which the pin could either be raised or lowered. From that period the shape of the trephine has practically remained unaltered, although the saw has passed through many modifications. Examples of the instruments mentioned, illustrating the origin and development of the trepan and trephine from ancient times, may be seen in the Historical Section of the Museum at the Royal College of Surgeons of England, to which an excellent guide[1] has just been issued.

SPLENO-MEDULLARY LEUKÆMIA.

THE occasional association of spleno-medullary leukæmia with trauma has been noticed from time to time, and the injury has been regarded as an important ætiological feature by more than one writer. Dr. S. C. Lewsen records a new case on p. 288 of this issue and quotes a large number of other cases from literature. To these may be added one just reported by Dr. Annelise Wittgenstein.[2]

The patient, a railwayman of 42, had never been ill until one day he fell on the ground and one of his mates tripped over him. The only apparent result was a slight effusion of blood from the leg. He remained at home for a month. Soon after the injury he started to complain of pain in the foot and loss of appetite, with heavy day sweats. He suffered from general debility and lost weight. Nevertheless, he continued to work under regular medical supervision for the next four months, during which time the cause of his poor condition remained undiagnosed. He died eight months after his injury, and the blood counts made in hospital admitted no doubt of the diagnosis of myelogenous leukæmia, the only unusual feature of the case being the normal size of the spleen. The number of red cells and the hæmoglobin index were greatly reduced, the figures being 1,600,000 and 35 per cent. respectively. The leucocyte increase, as is usual in the acute condition, was moderate, the count giving only 20,000.

It proved impossible to ascertain whether the patient had substained a blow in the region of the spleen, but Wittgenstein thinks that a severe shaking, especially if combined with contusion of the abdomen and the long bones, may be enough to lead to leukæmia in predisposed persons. He thinks that the cause is to be sought in exogenous influences of toxic, mechanical, or infectious origin. The reference to "predisposed persons" seems to bring this author nearly into line with those who believe that trauma does no more than reveal a pre-existent disease. This opinion is very widely held. Prof. Salvatore Diez,[3] for instance, who lately collected 30 cases of a supposed association, came to the conclusion that they afforded no proof that leukæmia could originate from a blow.

FIRST-AID IN ELECTRICAL ACCIDENTS.

IT cannot be too widely known that electric shock hardly ever causes death outright. Dr. D. Pometta, principal medical officer of the Swiss Accident Insurance Institute, has recently given a useful résumé[4] of the various methods of treatment which will probably save the victim's life if applied promptly and patiently. Such measures should be as familiar as the first-aid treatment of the common forms of poisoning, and the practitioner living in a district where accidents of this kind are particularly likely to happen will do well to have his apparatus packed in a special case ready to take up at a moment's notice. He should put aside all other work to answer the call to an electrical accident immediately, and should be prepared to stay by the patient for several hours. As soon as the victim has been removed from the danger zone, his mouth should be freed from dirt and any other obstacle to respiration, such as artificial teeth, and clothing should be removed from the upper part of the body, preferably cut off to save time. He should be kept warm with blankets and hot-water bottles or heated bricks, but zealous assistants must be warned of the danger of causing burns. The face and chest may be splashed with water, the limbs and cardiac region may be massaged, and cardiac and respiratory stimulants such as lobeline may be given subcutaneously; but none of these secondary requirements must delay or interrupt artificial respiration—the essential treatment—for more than a few seconds. While pointing out that prompt and correct application is more important than the choice of any special form of artificial respiration, Pometta prefers the Sylvester method. Here he is in a minority, for most authorities agree with Prof. S. Jellinek[5] in recommending Schäfer's. He regards manual methods as better than mechanical, but says that apparatus may be useful to replace assistants when everyone is tired out. Carbon dioxide is a valuable respiratory stimulant, and can be given from a soda-water syphon when no cylinder is available. The syphon is half emptied and a rubber tube is attached to its nozzle; it is then inverted and the fluid is blown out of the glass tube. Gas is admitted to the patient's air passages through one nostril, while artificial respiration is maintained continuously. Unless the patient's other injuries are so severe that he cannot possibly be alive, respiration must be continued for at least five hours, and the absence of the sounds of heart or respiration or of the corneal reflex are no indication that he is dead.

Sir Thomas Legge, who retired from the position of Senior Medical Inspector of Factories in 1926, has joined the staff of the Trades Union Congress as adviser to the Social Insurance Department on the health of workers as affected by conditions arising out of their employment. His work will lie primarily in the prevention of industrial disease and disability, and he will continue by pen and word of mouth to keep the trade-union movement informed on the problems of health in industry. There is undoubtedly a still untapped source of study and research in the sickness records of the big trade-unions in this country.

INDEX TO "THE LANCET," VOL. II., 1929.

THE Index and Title-page to Vol. II., 1929, which was completed with the issue of Dec. 28th, is now ready. A copy will be sent gratis to subscribers on receipt of a postcard addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

DONCASTER ROYAL INFIRMARY.—The report for the year ending Sept. 30th, 1929, shows that 1805 patients were admitted, who stayed for an average of 25·13 days, as compared with 23·4 days in the preceding year. New out-patients numbered 7143, an increase of 745; there were 3786 casualty cases and the attendances and treatments in the massage department were 27,416. A supply of radium to the value of £3000 has been given by Mr. William Nuttall. During the year Dr. H. J. Clarke, who has since died, celebrated his fifthieth year of general practice in Doncaster and was presented by his colleagues with a piece of plate. Dr. Clarke handed over to the hospital the balance of the Presentation Fund, amounting to £75, with the proviso that the income should be used for the purchase of a medal to be awarded annually to the best nurse of the year. The well-arranged and informative report sets out that the cost per bed was £129 8*s*. 9*d*., a reduction of 12*s*. 5*d*. The cost per in-patient was £8 16*s*. 10¾*d*., and per day 7*s*. 0½*d*.; out-patients cost 9*s*. 6*d*. The first block of the new Infirmary, containing 150 beds, with accommodation for 85 nurses and maids and the usual accessories, is approaching completion. The Doncaster Collieries Association has contributed £10,000 towards the cost.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

LXII.—INTERPRETATION OF REPORTS ON LESIONS OF THE EYE.

PART II.*

IN the first part of this article I dealt with definite organisms. When questions arise on the interpretation of the results of tests, such as the Wassermann reaction or Pirquet's test, the answers are less easy. The modern tendency to rely more and more on laboratory tests and less and less on clinical experience and knowledge imposes a responsibility on the bacteriologist which is unfair both to him and to the patient. It must be reiterated that laboratory tests, no matter how reliable, form only part of the data essential for correct diagnosis.

The Wassermann Reaction.

It often happens that a patient is sent to a laboratory for a Wassermann reaction. The result is positive—and without any further consideration the patient is passed on to a V.D. department, the eye condition being labelled "syphilitic." Further consideration may prove that the eye condition is due to septic teeth and the positive Wassermann to a congenital taint which requires no treatment. It is the clinician's job to elucidate these facts, not that of the person making the test. I am not suggesting that it is wrong to treat a patient with a positive reaction as a syphilitic, but only that it is wrong to label an eye disease as syphilitic on a positive Wassermann reaction alone.

Reports on Patients with Iritis.

The interpretation of the reports on investigations designed to elucidate the cause of iritis is difficult. The causes are so many and varied that it is often impossible to say with certainty what variation from the normal is responsible for the iritis. It may be accepted that iritis and iridocyclitis are, as a rule, the result of toxic irritation due to some distant septic focus. It is, indeed, rare to examine a patient without finding some septic focus, a suspicious tooth, infected sinus or antrum, a collection of pus behind a deflected septum or septic tonsils; any of them may be the cause (and equally may not be the cause) of the iritis. There is one cause of iritis in men which should always be inquired into—viz., gonorrhœa. In women gonorrhœal iritis is extremely rare. I have never seen a case. The history of gonorrhœa, however, is not enough, and in my V.D. department all the other causes of iritis are gone into before the patient is examined for evidence of an old gonorrhœal infection. Gonorrhœal iritis seldom occurs during the acute urethritis stage of the disease, and the average time after the acute attack of gonorrhœa at which the iritis appeared worked out at 9 years in one series of 250 cases, and 14 years in another series.

Significance of Pus and Gonococci—

Having assessed the importance of any other septic foci the next step is to examine the patient for evidence of a residual gonorrhœa. Urethritis and gleet are rare at this stage of the disease, and it is only when we come to the examination of the material expressed by prostatic and vesicular massage that evidence of the original infection appears. It is quite usual to find pus in considerable quantities, but is quite unusual to find the gonococcus, and although at one time I was finding the gonococcus in 9 per cent. of the cases of rheumatic iritis sent to my department for examination, my last figures worked out at 3 per cent., due to a more critical definition as to what was a gonococcus in the slides examined. Perhaps even this is too high a percentage. The difficulty of detecting the gonococcus amongst the débris of pus cells, spermatozoa, and organisms in the smear is so great that a definite statement is rarely possible. However, when pus has been found in the prostate or vesicles, treatment has to be carried out in spite of inability to find the gonococcus in the discharge, and the condition is labelled gonorrhœal iritis. The report made on a prostatic massage will often record the finding of all sorts of other organisms, streptococci, staphylococci, pneumococci, colon bacilli, and diphtheroids. These are probably the results of secondary infections and must be taken into consideration when arranging a course of treatment. This should consist of (1) the symptomatic treatment ordered by the ophthalmic surgeon, such as atropin, leeches, hot bathing, &c.; (2) specific treatment, such as vaccines, prostatic and vesicular massage, irrigation, &c.; and (3) treatment to clear up other septic foci.

—and of Rheumatic Pains.

Rheumatic was at one time frequently applied to what we now know is often gonorrhœal iritis. Rheumatism is almost always present in the history of patients who come with gonorrhœal iritis. Considering the small percentage of cases in which the gonococcus is found it is naturally open to debate as to whether these cases should or should not be diagnosed as gonorrhœal iritis. I myself use this classification, because the cases of iritis in which I find pus in the material from the prostatic massage are the cases which react to gonococcal vaccine. The reaction may be one of exacerbation of the existing iritis, or one of rapid cure of the condition. I believe that gonorrhœal iritis is a toxic condition and that the gonococcus is not present in the eye. Dr. Eric Biddle, when he was working with me at Moorfields, made the observation that it was quite rare to find gonorrhœal iritis in patients who had clean mouths, or perhaps it would be better put that people with septic teeth were more likely to get gonorrhœal iritis than those with clean mouths. This may account for the comparative rarity of the condition in private practice and certainly one of the first things to do in treating these cases is to have the mouth attended to.

Tuberculin Tests.

The tests for tuberculosis of the eye are few, and of little real value as proof tests. The only one of any real value is the subcutaneous injection of tuberculin, with resulting focal, local, and general reaction, but this test is practically debarred from use in eye work, since it is inadvisable to risk stirring up a tuberculous eye by a focal reaction. The graduated Pirquet test, using human and bovine tuberculin, is of some value if the results are used with discrimination, although the test cannot give definite information like the subcutaneous test.

If the result of the test is taken into consideration with the clinical evidence it is of help in young patients, and in adults may be a useful guide as to the type of tuberculin to use in treatment. The presence of a positive Pirquet test does not mean that the eye condition is a tuberculous one.

RADIUM THERAPY.

AN ACCOUNT OF A VISIT TO THE RADIUM INSTITUTE OF PARIS.

By J. W. NANKIVELL, M.B., B.S. LOND.,

LATE ASSISTANT TO THE RADIUM COMMITTEE OF MIDDLESEX HOSPITAL.

I HAVE just concluded a six months' visit to the Radium Institute of Paris, during which period I served as *stagiare* or clinical assistant in the different departments. A few days sufficed to show me why this Institute has gained such a high international reputation for itself and its workers. Here was the opportunity to see and later assist in the treatment of patients, mostly suffering from cancer, by surgery, radium, X ray therapy, or combination of any of these methods, as appeared indicated for each case. Here were patients consulting for advice, not at the surgical, radium, or deep therapy department, but at a clinic in which each department was represented. Each patient thus received the benefit of advice, entirely unbiased, as to what was considered the best line of treatment. Having been detailed to the appropriate department, the patient now had the benefit of coming under the care of a specialist in radium therapy, X ray therapy, or surgery, as the case might be. Some cases required more than one specialist's care, the preliminary examination by each deciding the details of the conduct of the treatment. In the follow-up clinic for treated cases the presence of representatives of all three departments encourages in each an appreciation of the possibilities of the methods of his colleagues. The biased opinion which often results from ignorance of the other side of the problem thus tends to become eliminated.

My visit has convinced me of the absolute necessity for specialisation of a large number of medical men in the field of radium therapy. Without such specialisation, and as long as radium therapy is practised widely by those whose ignorance of its limitations and dangers is equalled only by their enthusiasm to wield this new-found weapon against cancer, radium is merely a menace to the safety of those sufferers to whom it is applied in an attempt to cure. The main line of advance in the treatment of cancers by radium on the continent has been by the evolution and perfection of surface therapy, which has now superseded radium-puncture and the implantation of seeds, the methods popularly used in England to-day, as being the method which most nearly gives the ideal irradiation, uniform and homogeneous, by highly selective gamma rays. The lack of large quantities of radium has long held in check the possibility of exploring widely this field of radium therapy in this country.

With the creation of the National Radium Fund, which has reached nearly £300,000 and the appointment of a Commission to deal with the purchase and distribution of radium, the time has come when the importance of this line of radium therapy must be realised to the full if radium is to be utilised to the best advantage, and, more important, if patients are to receive what is due to them, the best and most effective treatment available. Surface therapy requires an entirely different equipment to that demanded by radium-puncture. The present tendency to put up all radium into small needles of varying lengths and charge, of varying filtration, usually 0·5 Pt. wall or less, though it produces a supply of radium very well suited to radium-puncture, also renders the same supply ill-adapted to surface therapy. It therefore seems justifiable at this juncture to put forward a plea for the serious consideration of the merits of surface therapy, and the setting aside of a considerable proportion of the radium to be purchased for the country for the purpose of testing its efficacy over a reasonable period, on suitable cases, in large enough numbers to form definite conclusions as to its superiority or not over radium-puncture.

The Commission has already shown great judgment in testing out "bomb therapy" on similar lines. Bomb therapy is only a modification of surface therapy demanded by the weight of the heavy lead protection required to protect patient and personnel from the rays emitted by the large charges utilised for treating deeply seated growths. Whilst the bomb of four grammes has but limited scope, owing to its fixed size, shape, and charge, surface therapy from which it has evolved has a very wide scope. It consists essentially in the formation of small radiant surfaces, of varying size, shape, and distance from the skin or mucous membrane to which it is moulded, which can be made to produce a very uniform and homogeneous irradiation of tumours at different depths by variation of distance of application and charge of radiant surface. Prof. Regaud and his collaborator, Dr. Lacassagne, have in recent lectures here and in America given a clear account of the evolution and growth of radium therapy, the underlying principle governing its use, their ideas on such matters as radio-sensitiveness and radio-resistance. It is my intention merely to mention briefly the methods I have seen applied to three sites of cancer—namely, the tongue (including floor of mouth), the skin, and the cervix uteri. Space does not permit details, and I am avoiding the error of mentioning average doses, except in the case of the uterine application, where doses vary less than in other sites.

GENERAL PRINCIPLES OF TREATMENT.

Certain general principles are applied at the Radium Institute of Paris, whatever be the site of the lesion or the status of the patient.

1. *Selection of Cases.*

(*a*) Elimination of patients in whom distant secondary deposits in the viscera and elsewhere are suspected on clinical and special examination.

(*b*) Elimination of those whose general health is such that they would not support the severe treatment necessary for cure without grave danger to life.

(*c*) Concentration chiefly on those cancers which react most satisfactorily to radium and X rays. Such are at present the epithelial cancers of epidermic origin, arising in the skin or mucous membranes covered by stratified pavement epithelium; certain sarcomata; some cancers of the prostate and breast.

(*d*) Elimination of all cases who have been previously treated by radium or X rays by other private clinicians or at institutions, unless they bring or can produce a statement of dosage received and details of treatment.

The importance of this rule cannot be over-emphasised. A vast experience of the radiotherapy of cancers has convinced these workers of the importance of taking strict precautions against the rule being broken, save in exceptional circumstances. They believe that a cancer, once treated by radiotherapy, becomes resistant to further irradiation. At the same time the normal tissues become more sensitive to rays after a previous irradiation. Each subsequent treatment will have to be more severe in order to overcome the more resistant cancer.

A second, and, still more, a third or a fourth treatment, whilst standing a poorer chance, therefore, of curing the cancer than would have done the first treatment, becomes more and more harmful to the normal tissues. Too often, in such cases, cure of the cancer is bought at the price of an extensive necrosis of the normal tissues, the production of which is as often as not as dangerous to the patient as was the cancer itself.

2. *A Preliminary Biopsy.*

This is required in every case, and the report received before treatment is commenced. *In certain* cases biopsy has to be omitted for obvious reasons, either till operation, or altogether, but these cases are exceptional. Biopsy is usually performed at the first out-patient consultation.

3. *Single Treatment.*

The belief in the gradual vaccination or onset of radio-resistance of irradiated malignant tissues to the further action of rays has led to the recognition of the necessity of giving the whole treatment within a comparatively short period before this complication has time to make itself seriously felt. A treatment which aims at being curative should, therefore, be complete within about three weeks. The single *treatment does not infer that only one technique* shall be utilised. One technique may follow another, but all should be complete within the stated period.

4. *Dosage.*

Although experience has taught that some varieties of cancer are more sensitive than others to irradiation. yet it is considered preferable at present to treat all cases by the biggest dose compatible with the health of normal tissues, until research has given more certain data on which dosage can be based.

The physical dose is measured in millicuries destroyed, and all radium tubes are designated according to the hourly destruction of radon which the radium content is responsible for. As none of the tubes represent an hourly destruction of more than a fraction of a millicurie, they are designated in terms of microcuries (1/1000 Mc.) destroyed per hour. The standard tubes used represent 100, 50, and 25 microcuries destroyed per hour (ucdh), or 13·3 mg., 6·6 mg., and 3·3 mg. radium element. The filtration is 1 mm. Pt.; exceptionally, in a few special tubes, 1·5 mm. Pt.

All radium-puncture is performed with radon, utilising hollow needles of 0·5 Pt. wall, 25 and 35 mm. in length, usually containing 1 Mc. per cm. active length, as initial charge.

Whether *radon or radium be used, the dosage is* exactly comparable, both being given in terms of Mcd., an advantage lost when such terms as mg. hrs. and mc. hrs. are employed.

The biological dose which is much employed in surface therapy is the epidermicide dose—i.e., that dose which produces a selective action on the basal cells of the epidermis, producing a "chute" of the epidermis, without damage to the dermis; the approximation of the intensity of irradiation received by the deepest part of a tumour to the intensity at the skin level is aimed at in surface therapy by so increasing the distance of the source from the skin and correspondingly increasing the charge that the falling off in the intensity between the skin and the tumour is not sufficient to prevent the dose to the latter being lethal. By producing always a chute of the epidermis, one thus ensures that the malignant cells, usually considerably more sensitive than the basal cells of the skin, shall also receive a lethal dose if the distance of the radiant surface and other factors of application have been rightly estimated. It seems superfluous to add that increase of the distance of application does not increase the penetrating power of rays, as I have seen stated.

5. *The Time Factor.*

At the Radium Institute much importance is attached to this factor. Five to ten days is the usual duration of treatment employed in most of the techniques utilised for reasons which are well known. The realisation of the fact that amongst malignant cells those in a state of division are more sensitive than others, and that all do not divide simultaneously, has led to the adoption of a longer exposure to a smaller charge of radium, which has proved more effective in sterilising cancers, at least in the case of the squamous cell carcinoma, whilst being less harmful to the normal tissues.

6. *Homogeneous Irradiation.*

Improved results of radium therapy have resulted from the gradual increase of filtration, suppression of beta radiation, and even the softer gamma rays where feasible, avoidance of secondary radiation by secondary filtration, and improved methods of distributing the selective gamma rays uniformly throughout the malignant tissue.

Radium-puncture, once much in vogue, has given way to surface therapy, except in a few situations where it remains still the best method at present; such situations are the tongue, uvula, certain cancers of the breast, and deeply infiltrating skin cancers. These small needles, whose walls fail to exclude all the beta rays and soft gamma rays, with their weak charge, whose intensity of irradiation, strong immediately around the tube, falls off very rapidly away from the source, require very careful introduction into an easily accessible tumour to render success at all likely. The near presence of bone contra-indicates their use in many situations, owing to the damaging effect of primary and secondary beta caustic rays. This technique has, therefore, a limited use at the Radium Institute of Paris.

TREATMENT OF SPECIAL LOCATIONS.

Cutaneous Epitheliomata.

The method of *moulded plaques of Colombia* paste of variable size and thickness is in general use for epitheliomata occurring on the skin and accessible mucous membranes, such as the inner surface of cheek and floor of mouth. The general principles remain the same in whichever part of the body the application is made.

The area to be treated, usually allowing ½–1 cm. outside the areas of clinical invasion, is marked out accurately with skin pencil, and a layer of paste, softened in warm water, applied with the firmer, woody surface next to the skin. When moulded it is dipped in cold water to set, reapplied, and the area marked on the skin projected on to the wax surface. This area is *carefully measured in* square centimetres. *The dose* required to sterilise a cancer depends on the area to be treated and the depth of infiltration. The thickness of the paste is in relation to the depth of the lesion, but the charge required to produce the *chute* of the epidermis varies not only with this, but also in relation to the total area, and the surface, whether convex or flat. These factors influence to a great degree the amount of cross-fire occurring; cross-fire increases with increase of area, increase of distance, and increase of convexity, and is minimal when the area, thickness, and convexity are small. The dose is ordered in terms of Mcd. per $cm.^2$; the total dose thus arrived at, and the number of days during which the apparatus is to be worn (4–7) being decided, the apparatus is charged with radium tubes of 1 mm. Pt. wall, of such charge that good distribution of tubes is acquired, and the number of hours a day during which it must be worn is calculated. The radiant surface so formed being covered with another layer of wax, it is strapped in position on the patient for the requisite time per diem.

Many patients whose lesions are conveniently situated can be treated as out-patients by utilising radon; such cases, usually with lesions of the forehead, face, &c., have to wear the apparatus continuously for 3–5 days and report each day for inspection. Later they report each day for dressing by vaseline gauze and inspection of the lesion until *all reaction has subsided and healing* complete.

The treatment of lesions of the inner surface of the cheek, lips, and floor of the mouth are based on the same principles and differ in no important respect from that above described, except that fixation of moulds in position is ensured by pressure of a cork plug in the case of the floor of the mouth and by moulding round the lip so as to take firm hold on the *chin in the case of the lower lip.*

TONGUE, FLOOR OF THE MOUTH, AND THEIR ADENOPATHIES.

For practical purposes it is useful to consider cancer of the tongue under two main headings, depending on its localisation in the anterior two-thirds or the posterior one-third. The treatment of these two groups differs considerably; when the lesion involves the floor of the mouth alone, the treatment again differs from that of either of the preceding lesions. When the lesion is less clearly defined, due allowance must be made and the treatment modified to suit the peculiar conditions present.

1. *Anterior Two-thirds of Tongue.*

Treatment is here directed to two distinct fields, the tongue and the neck.

(*a*) *Tongue Lesion.*—The treatment of the primary lesion of the anterior two-thirds is carried out by the well-known method of radium-puncture, the details of which differ but slightly from those of the technique commonly employed for similar lesions in this country. A uniform distribution of needles containing radon as previously described is possible with fair accuracy in lesions of limited extent. They are inserted without general anæsthesia after blocking the lingual nerve of one or both sides as required by novocain. They are sutured in position with silk and retained from five to seven days.

(*b*) *Treatment of the Glands.*—The results of operating on the glands of every case of carcinoma of the tongue treated for several years have shown that an important percentage of the glands clinically perceptible are not malignant. Further investigation shows that this non-invasion of the glands is more commonly associated with small unilateral lesions of the anterior two-thirds, and is less frequently associated with lesions of the posterior one-third and floor of the mouth. On the other hand, cases occur frequently in which no glands are clinically present but are discovered at operation and turn out to be malignant when examined microscopically. Therefore, irradiation of all cases would subject a considerable number of patients to unnecessary inconvenience and discomfort to no purpose, whilst non-treatment of cases in which no glands are perceptible would certainly be followed by the development in a certain number of glands which in due course would manifest malignant characters.

The present rule adopted where the primary growth is small, unilateral, strictly localised to the dorsum in its anterior two-thirds, and appears to have reacted well to local treatment by radium-puncture, is to treat the glands of that side by irradiation when they are clinically malignant. Where no glands are palpable, or, if palpable, they do not possess malignant characteristics, a block dissection is performed on the side of the lesion to ascertain the presence or not of malignant glands. If present, it may be presumed that the operation alone holds good prospect of cure under such ideal conditions before fixation is present and no further treatment is given. If malignancy is not present, the patient and surgeon are reassured as to the prognosis, and the patient has escaped the unpleasantness of a severe and useless irradiation.

In all cases other than those just quoted, irradiation of one or both sides of the neck is performed, and operation holds no place. That is to say, all necks are irradiated, usually bilaterally, in all cases of carcinoma of the anterior two-thirds (with the exception just mentioned), posterior third, and floor of the mouth.

The method of irradiation is on the same lines and involves the same principles as were indicated for the treatment of skin cancers by surface therapy. By increasing the distance so that the radiant surface is parallel to but situated at 6–8 cm. from the skin, and greatly increasing the charge of radium up to often ½ g. a miniature bomb is formed. The radiant surface is held at the required distance from the plaque of wax moulded to the skin by pillars of cork. The whole is surrounded by lead 4–5 mm. thick, the outer surface of which is again covered by wax to absorb secondary radiations. The radiant surface formed by fixing the requisite number of tubes of radium, screened by 1 mm. Pt., thus produces a well-distributed irradiation of the glandular field over which it is applied. The area treated is accurately measured and the dose given over eight to ten days which, experience teaches, will produce a selective chute of the epidermis, the apparatus being worn several hours a day, often ten, in a recumbent position with the neck well extended. The treatment of the other side follows that of the first, a useful cross-fire effect being thus produced.

The hours of treatment and discomfort of the patient might both be considerably reduced by the use of a suitable sized bomb of 2 g. or so in such cases, relieving the patient of the weight of the apparatus.

2. *Posterior Third of Tongue.*

In this lesion it is difficult and often impossible to produce a uniform irradiation by means of radium-puncture alone, owing to difficulty of access, and frequent extension to the vallecula, epiglottis, &c. It is not justifiable, therefore, to satisfy oneself with this treatment alone. It must be supplemented by an irradiation from the exterior.

The procedure adopted is to treat as efficiently as possible the lesion by radium-puncture on the usual lines, employing local anæsthesia. As soon as the treatment is finished, the supplementary treatment from the exterior is commenced by a bilateral application, first one side, then the other, as described for glands in the neck. This irradiation is designed to treat both the glands and the primary growth simultaneously, and for this purpose the radiant surface has to be arranged to reach a level which will permit irradiation across the base of the tongue. The total treatment takes three weeks. Hence operation to define the malignancy or not of glands is not justifiable, since the external irradiation is necessary for the cure of the primary and should not be postponed.

The time required for operation and healing would put off the supplementary irradiation ten days, during which time the primary is perhaps becoming resistant to further irradiation.

3. *Floor of the Mouth.*

In the treatment of this lesion radium-puncture is dangerous owing to the proximity of bone, and is likely to produce osteo-radionecrosis of the mandible whilst not curing the lesion.

Treatment is therefore planned so that a cross-fire effect is produced on the lesion by surface irradiation from within and without the mouth, using only the most penetrating rays, thus avoiding the possibility of bone complications as far as possible.

Treatment is commenced by moulding a suitable thickness (a few millimetres only) of Colombia paste to the lesion, charging it not too strongly, and aiming at the sterilisation only of the superficial part of the lesion. The apparatus is maintained in position several hours a day for five to seven days until a sufficient dose has been given. It is held in close apposition to the lesion by giving the patient a suitable rubber cork to insert between his upper teeth and the upper surface of the mould. By biting on this firmly during applications, not only is the mould immobilised but the upper jaw, lips, and tip of the tongue are held out of danger.

Internal application is immediately followed by external applications of large packs to both sides of the neck, which are modified to extend forward over the submental region, and are directed more upwards than in the case of the average apparatus for treatment of glands in the neck. This external application represents the most important part of the treatment of the floor of the mouth, owing to the large ports of entry permitted through the submaxillary and submental triangles of each side. Here, again, the importance of continuing the treatment of the primary growth uninterrupted must take precedence over any inclination to operate on the glands.

Where the lesion extends into the base of the tongue it is necessary to supplement the treatment by a radium-puncture confined to this region, which cannot be treated by the surface application successfully. Great care must be exercised not to carry the radium-puncture farther forward than is strictly necessary.

Where the lesion already involves the bone, necrosis must inevitably occur if cure is to ensue. The necrosis is, however, more limited by employing the technique described than is possible when methods such as radium-puncture and seeds are employed, with their inevitable caustic radiation.

CERVIX UTERI.

The method employed is intracavitation radium therapy, by the application of a uterine sound of rubber containing a variable number of radium tubes according to the length of the canal previously determined, and a vaginal applicator, the colpostat, which consists essentially of two cylindrical hollow corks, held apart by watchspring, each containing a radium tube.

The uterine sound is rendered semi-rigid by introducing into it a cylinder of thin aluminium 1/20 mm. thick. The tubes inserted in an ordinary case are two of 13·3 mg. and one of 6·6 mg. Ra. el., all having a wall of 1 mm. Pt. In each cork of the colpostat is placed a tube of 13·3 mg. The spring and corks are wound round with rubber and collodionised. A central cork containing 6·6 mg. Ra. is usually inserted between the cervix and the spring of the colpostat, each cork of which rests in a lateral fornix. All tubes used in the vagina have a primary filtration of 1·5 mm. Pt.

This application is performed without anæsthesia, with but little discomfort except a little during dilatation. A light packing to maintain the central cork in position is all that is necessary. The whole outfit is removed daily, sterilised whilst the patient receives a vaginal douche, and reinserted. The apparatus is retained for five days, except for such daily removals.

Such a treatment giving a total dose of 60 Mcd. or approximately 8000 mg. hrs. may be said to be typical. Actually, whilst the dose varies but little, the number and strength of foci used are greatly varied to suit the individual, by the addition of further uterine tubes and the insertion often of two or three central corks, always accompanied by a corresponding decrease in the strength of tubes, a 13·3 mg. tube being replaced by two 6·6 mg., so that uniformity of irradiation may be as complete as possible.

This treatment unsupplemented is considered effective only for Grade 1 cases, where disease is confined to the cervix. In all other cases supplementary treatment by deep X rays or radium at a distance is held to be essential, and is always given, either before or, more usually, after the local treatment. In this region, deep X rays seem to give results as good as those by bomb therapy as a supplementary treatment.

Various techniques employed in England to-day, whose local treatment probably falls far short of the efficacy of the above-described treatment by colpostat and sound, do not include any supplementary treatment to the parametria and pelvic glands. Little wonder that certain gynæcologists still regard operation as preferable to irradiation. A well-planned operation seems preferable to a half-hearted irradiation, but it is to be hoped that the latter method will disappear, and give place to a whole-hearted, well-planned treatment by radium and deep therapy combined, which may be capable of improving on the results of the best operative technique.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Physical Welfare at Edinburgh University.

THE Edinburgh University Court has appointed Colonel R. B. Campbell as director under the scheme for the promotion of the physical welfare of students and the development of University athletics. Some years ago Dr. Tait Mackenzie, of Pennsylvania University, lectured in Edinburgh on the need for placing the physical welfare of students on a sound medical footing. In his own university he has charge of the health of all the students, grading their exercise (or no exercise) to suit the physical condition on entry and throughout the curriculum, and selecting from time to time those who show special aptitudes for the heavier games. In a University of some 10,000 students this is an onerous task, but Dr. Mackenzie seemed satisfied that the general results were good. His sculptures show what ideals he aims at.

In Edinburgh, where the number of students approaches 4000 (men and women), the University has not seen fit to appoint a qualified medical practitioner, but a distinguished army officer. His record commands respect; but the physical welfare of the students, it is hardly necessary to say, is not even primarily a question of athletics; it is first a question of health and adaptation of selected exercise. For many years the students at the Provincial Training Colleges have been under medical supervision and each has access to the doctor. About twenty years ago the Scottish Education Department succeeded in displacing the drill sergeant from the elementary, higher grade and secondary schools, and in securing the appointment of a superintendent of physical education trained by the College of Hygiene in Dunfermline or places of similar standing. The system of physical education in all classes of schools is now well organised and under the direction of the medical officer of the department, who also inspects the hygienic training of teachers at the colleges. The idea now being pushed forward is that physical education shall come more and more under the direction of the school medical officer.

The problem at the Universities is different and perhaps the University Court may mean to place an adequate medical staff at the disposal of the director. The matriculation fee has been increased by 10*s.* a year to form a physical welfare fund. Lord Constable's Committee also recommended that an officer of the University should be appointed to direct in a general way the athletic activities and the physical culture of students. The work of the director is not, therefore, confined to athletics. He has himself been inspector of physical training in the army and experience will have taught him where the weak points in candidates for physical culture lie. But, in the end, if the system is to succeed in fitting the student to his work, the physician and the surgeon will both have to come in at some stage. It cannot be assumed that the big proportion of students unfit for violent games are to pay an extra fee merely that the more fit may be better equipped and trained. It is not necessary now to say anything about the correlation of cerebral with muscular training. But the problem is far from simple.

Night Baking.

The proposal to abolish night baking has caused considerable disturbance in the Glasgow trade. It is alleged that only a small proportion of the employees will benefit from the abolition and a large proportion will be seriously disadvantaged. The price of bread, and particularly of rolls, it is said, will certainly rise. During the war, when an officer of the Scottish Board of Health in order to economise consumption suggested that no bread should be sold that was less than 30 or 48 hours old (I forget the exact figure), the great objection was that this would involve expansion of premises in order to accommodate the accumulated loaves. By the present system they are cleared out at the earliest possible moment. Probably the same difficulty would arise from the abolition of night baking; for some of the Glasgow employers seem to make a point of providing fresh bread and maintain that bread half a day old, or even a day old, would be stale. This, of course, is nonsensical. The objection to "stale" bread is a matter of taste, many consumers preferring it to fresh bread. There is, however, no doubt that the abolition of night baking will involve a very serious rearrangement of hours and duties. It is to be noted that the abolition of underground bakehouses took about a generation to accomplish. There is a doubt whether it is fully accomplished yet; to the small shop-keeping baker the convenience of the underground bakehouses is so great as to over-ride every other consideration. The employees of the Edinburgh trade meet all these points in detail, and point out that the abolition of night baking was recommended after a full inquiry into all the conditions.

Edinburgh Death-rate.

The Edinburgh death-rate for 1929 was 15·1 per 1000 as against 13·7 per 1000 in 1928. The increase is said to be due to the influenza epidemic and to 638 deaths from pneumonia. The infantile mortality was 80 per 1000 births as against 75 per 1000 in 1928. The population shows a tendency to decrease. There is considerable shifting of population within the City itself. One striking fact is that not a single death from measles has been recorded in the City since July, 1928. This is probably a record. In the years 1893–95 measles swept away hundreds.

Dr. William Macrae Taylor.

By the death of Dr. Macrae Taylor Edinburgh has lost one of her most attractive personalities. Dr. Taylor was not merely a widely educated physician and surgeon, but also a man with a gift for social affairs. He was ready to do work that medical men do not as a rule find interesting. For example, he acted for a period as treasurer to the Medico-Chirurgical Society and the Obstetrical Society, as well as to the Tuberculosis Society. This meant a great deal of correspondence and troublesome detail. But Taylor used the occasion to bring harmony and coördination into the working of the various societies, and he did so with the ease that comes of a large and pleasing temperament. For more than 25 years he was medical officer of Cargilfield School for boys, which is one of the best-known schools of the English public school type in Scotland. As far back as the Boer War he held a commission in the R.A.M.C. and in the Great War he did more than his share. He was a Territorial officer and at once volunteered for service abroad, going to France in 1915. In 1916 he became D.A.D.M.S. with the 69th Division. He also saw service in Italy, and in 1919 retired with the rank of Surgeon-Major. He seemed by nature adapted to offices involving responsibility and work was no trouble to him. In many ways the profession in Edinburgh has shown how much he was respected as a medical man and how much he is missed. He was a favourite all round and belonged, perhaps, less to the highly technical and specialised medicine of to-day than to the medicine of one or two generations ago when the larger men were not too much occupied to take an active part in the social life of a cultured city.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Hospitals and Lotteries.

A BILL obtained its first reading in the Dail before Christmas, the object of which is to grant powers to enable funds to be raised by means of sweepstakes and drawing of prizes for the support of public charitable hospitals and sanatoriums in the Irish Free State. A deputation of medical men connected with some of the Dublin hospitals waited on President Cosgrave last week to ask him to facilitate, as far as possible, the further passage of the Bill. Hitherto the Government has maintained a strict attitude in regard to sweepstakes and lotteries of all kinds, and has refused to make exceptions for hospitals or other charitable institutions. The deputation pointed out to the President that some of the Dublin hospitals are in a bad way financially, owing to the falling off of subscriptions and the increase of expenditure. The work of the hospitals is being hampered by shortness of funds. The President promised to give the representations made to him his best attention. Coincidently with the visit of the deputation alarmist rumours as to the position of some of the hospitals have appeared in the daily press. It is stated, for example, that unless some means of raising money is discovered a number of the Dublin hospitals must be closed. No hint is given as to the particular hospitals which are in this plight, and it is, therefore, impossible to investigate the accuracy of the statement. As far as can be discovered, however, no hospital has had as yet to consider the problem of closing its doors. While it is generally recognised that the problem of finance is a serious one to the Dublin hospitals, there is a good deal of difference of opinion, both in the medical profession and among lay governors of hospitals, as to whether sweepstakes and lotteries are the best way of raising money. There is the general objection to public lotteries which has induced most civilised Governments to declare them illegal. Apart from this, it is thought by many that the temporary relief which may be given by a successful lottery will be followed by a greater reaction, which will diminish further than ever the ordinary income of the hospitals from subscriptions. Much of the falling away in the income from subscriptions appears to be due to the generally accepted opinion that the hospitals receive an adequate income from the payments made by patients. If the public get the further notion that the hospitals have a gold-mine within their reach in the form of a lottery or sweepstake, subscriptions are likely to fall further.

Death of Mr. Kennedy Cahill.

The sudden death of Mr. F. Kennedy Cahill on Jan. 27th has come as a shock to many friends. He had been in his usual health when retiring the evening before. Mr. Cahill qualified in 1901, and was admitted to the Fellowship of the Royal College of Surgeons in Ireland in 1907. Having spent a few years in his younger days as poor-law medical officer at Dundrum, Co. Dublin, Cahill moved into Dublin and devoted himself to practice in the specialty of diseases of the stomach. He was much interested in art and literature, and had many friends among the artistic and literary people in Dublin. He was a kindly and simple character, liked by everyone, and never happier than when doing a kindness.

A HOSPITAL FIRE.—At 5 A.M. on Jan. 25th a night nurse at Bristol General Hospital gave an alarm of fire, and it was found that a room on the first floor used for developing X ray photographs was ablaze. Dr. S. H. Griffiths, the senior resident surgeon, and the night staff succeeded in keeping the fire within bounds until the arrival of the fire brigade, when it was speedily extinguished. There were 250 patients in the hospital and three wards were for a time in danger.

SYON PARK AND WEST MIDDLESEX HOSPITAL.—At the meeting of the Middlesex County Council at the end of last week there was some discussion upon the proposal of the Rivers Committee of the Council that a portion of the park of Syon House, Isleworth, should be taken for sewage disposal purposes. Captain Burgess pointed out the undesirability of establishing sewage works close to the West Middlesex Poor Law Hospital, Isleworth, which at present has 400 beds and will shortly have 700. It has been decided not to proceed with the proposal.

BIRMINGHAM HOSPITALS CENTRE.

AWARD IN DESIGN COMPETITION.

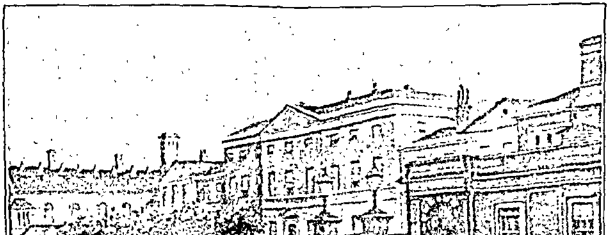
FOR many years past the Executive Board of the Birmingham Hospitals Centre has been giving earnest consideration to the subject of securing a closer coördination of hospital and medical facilities in Birmingham, and in the more recent years has devoted its activities to the preparation of a practical scheme for this purpose. The completion of a schedule of all known requirements was effected in 1929, when 12 architects were selected to take part in a limited competition for designs for a general hospital of 740 beds, a paying patients' block of 100 beds, and buildings for the medical faculty of the University. The faculty is at present housed in the city, some two miles from the present University site. The assessor's award has now been made, and the possibility, long in the minds of some of Birmingham's foremost citizens and doctors, of making the city the hospital capital of Great Britain, has been advanced an important step forward.

How the Scheme Arose.

The origin of the hospitals centre scheme goes back to 1920, when the city was able to resume normal conditions after the war. The ruling factor in the situation was that both the two leading voluntary hospitals, the General and the Queen's, had an increasing deficiency of beds relative to the demands made upon them and the growth of population. How was this deficiency to be met? Was the right solution simply to extend each hospital so as to provide the increasing accommodation required by civic needs and also meet the demands made by the growth of science in the many auxiliary services required? Each of these hospitals was in a densely populated quarter, and, apart from other considerations, expansion promised to be neither easy nor economical.

The medical school of the University was also concerned. Each of these hospitals was a teaching hospital for that school, and the medical staffs were closely linked up with the members of the medical faculty. The two voluntary hospitals, in fact, were not only hospitals for civic needs, but also an integral part of a coördinated scheme of the medical school; they were the chief centres where medical students would be trained and facilities provided for the advance of medical knowledge, for research, and for linking up the clinician with the scientific personnel of the University departments in such subjects as anatomy, physiology, pathology, bacteriology, and biochemistry.

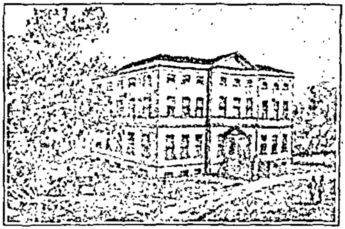
FIG. 2.



The same in 1895 just prior to the move.

Growing Hospital Developments.

FIG. 1.

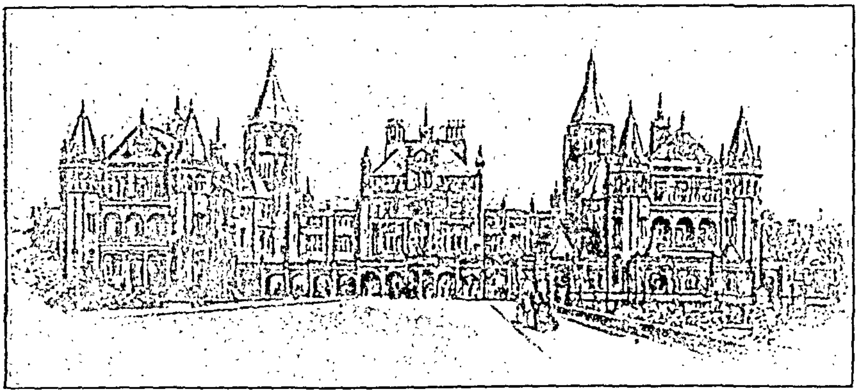


The old Birmingham General Hospital in Summer-lane, opened in 1779.

The Board kept constantly in mind the triple function of a voluntary hospital which is also a teaching hospital—namely, (1) to provide the best medical treatment available for its patients; (2) to be a school for the training of future members of the medical profession and also, not less important, the nursing profession: and (3) to be a centre for the advancement of medical knowledge and science, which cannot be separated into a compartment by itself but must be linked with other scientific departments in the University, such as biology, chemistry, and physics. Each of the two hospitals concerned evolved a separate and independent extension scheme, and this brought the whole situation to a head. By that date—i.e., about 1923–24—many of those most deeply interested were aware that in other great industrial and civic centres, both in Great Britain and on the Continent, the right solution of the hospital problem was being found in going outside the main centre of population and building up on unoccupied ground a hospital centre, with free ground for expansion as the future required, and for linking up with all sorts of subsidiary and specialised institutions. The same argument had prevailed in 1900, when it was decided by the founders of the University to establish a University quarter at Edgbaston.

Science and medical science continuously develop. It is impossible to predict what form they may take or what requirements are essential to meet their needs, and those who advocated a hospitals centre for Birmingham felt that no extension, however considerable, of the General and the Queen's would really meet the demands of the future; it would be at best only a temporary solution for this generation. But where was the site for this centre to be found? This was both a question of money, of hospital, and of medical school requirements. The argument already outlined indicates that the new hospital ought to be somewhere in immediate relation to the University, and particularly its scientific departments. The latter had already migrated to Edgbaston, but so long as its two central teaching hospitals remained on their present sites it was impossible to transfer the medical faculty from Edmund-street to the Edgbaston site.

FIG. 3.

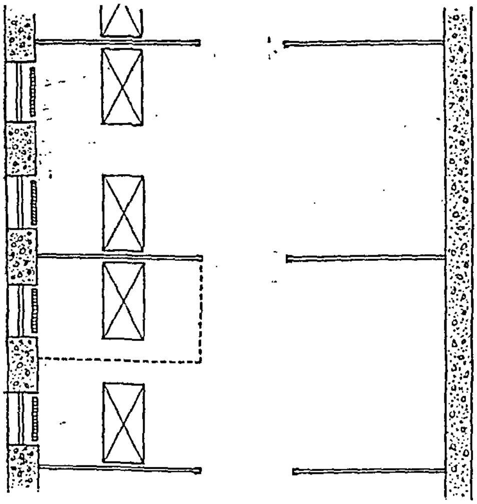


The new General Hospital in Steelhouse-lane opened in 1897.

Amalgamation on a New Site.

Agreement was reached at last when Messrs. Cadbury Bros. offered to the city 150 acres of land at Edgbaston lying to the north-west of and immediately adjoining the University buildings. It was only necessary to allocate (say) 25 acres of this new site to provide everything that a hospitals centre for the next 20 years would require, and which could then be linked up definitely with the University on the other side of the canal. The next step was to bring the General and Queen's Hospitals into agreement, and a joint committee was formed of representatives of both hospitals, under the chairmanship of Sir Charles Grant Robertson, to investigate the problem and recommend a solution. The committee's report contained the two main points: (1) that the new hospitals centre should be established at Edgbaston and should be under the joint control of the General and Queen's Hospitals—that is to say, it was to be a joint extension of both hospitals, taking the place of the separate extensions which had been contemplated and prepared; (2) that in order to achieve this satisfactorily, the General and Queen's Hospitals "should be amalgamated for all purposes."

FIG. 4.

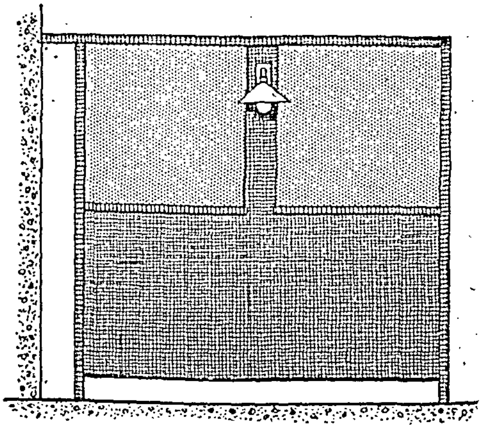


Plan of a ward unit with the new lengthways arrangement of beds.

Both hospitals having accepted these and the other recommendations in the report, an Executive Board was set up for the new hospitals centre with Sir Charles Robertson as chairman. Its first function was to make a detailed and technical scheme. Commissions were sent to the Continent and to the United States to study recent developments in hospital design and organisation, and a scheme was framed on the basis of the reports of these commissions. Finally an architects' competition was arranged with Mr. Percy H. Adams, F.R.I.B.A., as assessor.

Concurrently with the investigations of the Executive Board, the whole question of the organisation of the medical school has been under the careful consideration of the Medical Faculty of the University, and which has been kept in close touch with the Board's deliberations. It was the function in particular of the Faculty to decide on the character and requirements of the medical school as a school of the University, and their recommendations were finally accepted by both the University and the Board.

FIG. 5.



Elevation of the screen which separates the heads of adjacent beds in the new ward arrangement.

A Scheme with Three Aims.

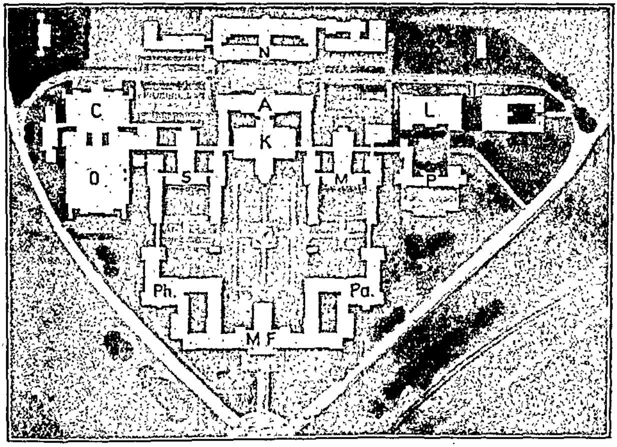
Three main characteristics of the scheme make it unique for Great Britain.

1. The hospital proper will represent the latest ideas and experience in the design, planning, and administration of a hospital considered simply as an institution for the treatment and cure of disease. Neither trouble nor investigation has been spared in order to see that this aspect has been fully met. When the scheme is completed Birmingham will have a hospital at least the equal of any in the world.

2. In accordance with the trend of modern ideas and needs, the scheme includes a big block, also designed on the most modern lines and in close relation to the hospital proper, for paying patients. The Birmingham citizen who does not come within the ordinary category of hospital patient will thus enjoy at the lowest available cost the advantages of institutional treatment and will have at disposal all the skill and experience of the medical, nursing, and administrative staff. The new hospital centre is to serve the needs of *all* classes of citizens.

3. There will be close and integral connexion between the scientific departments and buildings of the medical school and those of the hospital proper. Both the Board and the Faculty were agreed that the link between the scientist and the clinician was essential for the treatment and cure of disease, no less than for the training of students and for the advancement of medical knowledge. In the proposed linkage between science and treatment, between the clinician and the scientist, between laboratory and ward, the centre will be working on the lines accepted in the newest and most progressive hospitals and medical schools on the Continent and in America.

FIG. 7.

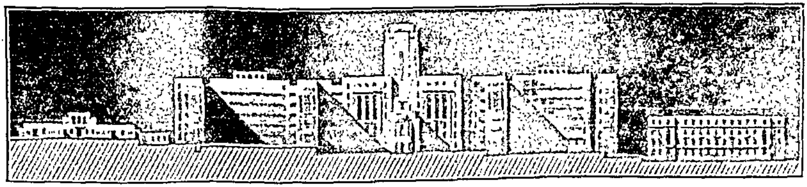


Site plan of the same showing completion of the quadrangle by the medical faculty building on the south.

C = Casualty. O = Out-patients. S = Surgical block. M = Medical block. K = Kitchen. A = Administration. N = Nurses' home. P = Paying patients. L = Laundry. M.F. = Medical faculty. Ph. = Physiology department. Pa. = Pathology department.

It is estimated that the scheme when completed will have cost something approaching £1,250,000. In carrying it through Birmingham aims at influencing scientific thought and civic progress elsewhere. Laymen and leaders of the medical profession in Birmingham have worked whole-heartedly together in the preparation of this scheme, but the decision finally rests with the citizens of Birmingham, to whom an appeal will be made in March.

FIG. 6.



Winning design for the Hospitals Centre in Edgbaston. South elevation of the hospital block.

Plan of the Wards.

In planning the wards it was suggested to the competing architects that the unit system should be adopted. Each member of the senior staff was to be provided with a unit of 60 beds and accessory services, such as clinical laboratories, record-room, operating-theatre (on the surgical side), for which he is responsible; all of them where possible on the same floor and under the control of one sister. The 60 beds were to be divided equally between the sexes, with, in either case, one ward of 16, two wards of 4, and three wards of 2 beds each. The architects were asked to think of the beds lying as far as possible parallel to the windows, instead of at right angles to them, which will result in an arrangement of the 16-bed ward familiar enough in America although not yet seen anywhere in this country; it is, however, we believe, on the specification for the new Southend hospital. The beds, as will be seen on the rough plan (Fig. 4), will back on to partition screens projecting 8 feet into the ward; each bed will thus have its own window and radiator on one or other side, no patient being compelled to look straight into the light. The arrangement makes it easy (as shown by the dotted line) to place a temporary screen round a particular bed which will still retain its own light and ventilation. The screen (Fig. 5) itself is of sheet-metal below with glass panels above, divided by a mullion carrying electric lamp, bell, wireless, and so forth; for cleanliness and ventilation the screen does not reach either the wall at the side or the floor below. The screens are placed 10 feet apart, and there is a clear space of 6 feet down the centre of the ward. This longitudinal arrangement of beds reduces by a couple of feet or so the width of the ward (which need only be 22 feet) and therewith the cost of construction by quite a large amount.

The Winning Design.

Prizes of £500, £300, £200, and £100 were offered for the four best plans sent in, and the winning design was submitted by Messrs. Lanchester & Lodge (19, Bedford-square, London, W.C. 1.), the others in order of merit by Mr. S. N. Cooke (Sun Building, Bennett's-hill, Birmingham), Mr. Charles E. Elcock (of Elcock and Sutcliffe, 21, Northumberland-avenue, London, W.C. 2), and Messrs. Pite, Son, and Fairweather (12, Carteret-street, London, S.W. 1.) bracketed with Messrs. W. and T. R. Milburn (10, Fawcett-street, Sunderland). Mr. Lanchester is the designer, among other things, of the Central Hall, Westminster, the University of Leeds, and the Cardiff Municipal Buildings, and is now carrying out the reconstruction scheme of St. Bartholomew's Hospital; his colleague, Mr. Lodge, has specialised in hospital work. Their design is a remarkable architectural effort; some idea of its impressive character may be gained from the elevation of the south aspect reproduced here (Fig. 6). The administration block is centrally placed with the chapel in the middle and the blocks of wards lying right and left of this central building; at the extreme end of the elevation to the left is the out-patient department and to the right the block for paying patients. The main access runs from north to south, with the nurses' home on the highest ground, then the hospital and, finally, nearest to the entrance from the University and stretching across the site with a main façade of over 600 feet, the medical faculty building with the library overlooking the road leading to the University. A glance at the site plan (Fig. 7) will show how every section of the hospital community seems to have been considered in regard to light and air, although one cannot avoid the impression that the nurses' home, situated so closely north of the administration block, will have much of its possible sunshine cut off in the winter months. The medical faculty is housed in a low building on the south side of the main frontage only two floors high, which will be a boon to the students attending lectures, who will be freed from the tiresome necessity of ascending and descending innumerable stairs. Inasmuch as all the buildings are planned inside a ring road it is feasible to connect them by covered ways and corridors. Communications are all well thought out, especially the service from the central kitchen, which, curiously enough, seems to err if anything on the side of being rather large.

MEDICINE AND THE LAW.

Workmen's Compensation: Effect of Wife's Ill-health.

A RAILWAYMAN, living in a country village in Lincolnshire, refused to go to any of the places where work was offered him. He had lost an eye in an accident in October, 1928, and was paid compensation at the rate of 30*s.* a week till February, 1929, when the weekly sum was reduced to 7*s.* 7*d.* His pre-accident earnings were over £3; the London and North-Eastern Railway, his employers, offered him work at £2 6*s.* 9*d.*, but he refused the offers because of his wife's ill-health, and because he could not get accommodation suitable for her and the family. The county court judge found that the work offered was suitable. The question was whether a workman was entitled, for the purposes of the Workmen's Compensation Act, to refuse to take suitable work in a different town on the grounds of the health and housing of his family. The county court judge declared himself unable to take into account the lack of accommodation, the wife's health, or the state of the labour market. The Court of Appeal has upheld this decision. The Workmen's Compensation Act, says Lord Justice Scrutton, excludes the consideration of the workman's ties to his family. "Supposing he had ten children and two of them were liable to consumption, he could not refuse suitable employment on the ground that his two children could not live in the place where the work was offered."

The point does not seem to have been decided before. This refusal of work in connexion with workmen's compensation (by a workman whose capacity has been reduced by accident but who is nevertheless able to earn in some suitable employment wages which will save his employer from paying him compensation as for total incapacity) must, of course, be distinguished from the topic, recently much discussed by Parliament, as to the steps which a man must take towards the positive pursuit of work in order to justify the receipt of unemployment insurance benefit.

CARBON MONOXIDE POISONING.

AN AMERICAN REPORT.

THE American Medical Association recently appointed a committee to consider the risks of carbon monoxide poisoning and the best way of preventing fatalities. This Committee has just published its first report,[1] drafted by Prof. Yandell Henderson.

In the course of this review it is stated that most of the cooking stoves and heaters in which gas is burned have the defect that the flame of the burning gas is chilled when it comes near a cooking utensil and the chilling stops combustion at the first stage, liberating carbon monoxide. Cooks who work with such stoves very often have the headaches which are typical of a low grade of intoxication by this gas. The defect can be remedied to a certain extent by increasing the distance between the orifice of the gas burner and the cooking utensil, which should be held just above and not in the visible flame. When patients are found dead in closed rooms where there is a stove or water-heater the accident is often attributed, not to carbon monoxide, but to "exhaustion of oxygen in the air by the fire." This explanation, however, is incorrect, for if the oxygen were reduced to 16 per cent. the fire would go out, but life would not be threatened until the quantity was down to about 8 per cent. All such fatalities are in reality due to carbon monoxide. Another risk to life arises from the fumes of burning buildings, where carbon monoxide is produced in great amounts and often overcomes the firemen. Similarly, in coal and other mines it is the carbon monoxide far more than the explosion that causes the death of the miner. Carbon monoxide produced from water-gas is being used more and more in industry as the starting-point for the manufacture of such substances as methanol.

Poisoning from Illuminating Gas.

The Committee points out that while gas is a common means of suicidal death it also causes a number of accidental deaths. The gas used in American cities to-day is formed either by the destructive distillation of coal, which produces a gas containing about 7 per cent. of carbon monoxide, or else by blowing steam through red-hot coal to produce water-gas, which contains 40 per cent. of carbon monoxide. The average city gas in the United States is a mixture of these products and contains about 20 per cent. of carbon monoxide. More than 500 deaths in a year are caused in New York City by an illuminating gas which contains a high percentage of the monoxide. One of the chief difficulties in the way of lowering this mortality is economy. Gas which contains a low percentage of carbon monoxide costs much more than a gas which contains a high percentage. For this reason the Committee thinks it important to educate public opinion to realise that the cheap thing is not the safest and that the best way of paying for gas is on the basis of the heat unit and not of the cubic foot. Scientific advances during the next few years may lead to the manufacture from cheap coal of a gas which is low in carbon monoxide, high in calorific value, and moderate in price. Such a gas need not involve many fatalities even when used in enormous quantities, and experimental investigations of the possibilities of producing it deserve liberal financial support. Meanwhile much could be done by the elimination of sheer carelessness. Individuals and public authorities in the United States go on countenancing the use of defective pipes and connexions and flueless water-heaters and geysers. Inadequate and cheap apparatus continues to be sold. The Committee recommends that gas should only be burned in appliances with fixed connexions, as even the best quality of flexible piping may become disconnected. It also suggests that the municipality should be responsible for seeing that flues are provided for water heaters and stoves, and furnaces and connexions periodically inspected.

---

[1] Jour. Amer. Med. Assoc., Jan. 18th, p. 179.

Motor-car Dangers.

The combustion of air and petrol under pressure in the modern car is never complete and the exhaust gas always contains some carbon monoxide, which may reach as much as 7 per cent. when the carburettor is set to supply a rich mixture for quick starting-up in traffic. Roughly, for each 20 h.p. of the motor, one cubic foot of carbon monoxide is produced each minute. The Committee suggest that the newspapers should publish each year before the cold weather begins warnings against starting an engine in a closed garage. The memory of the public is short and, although many deaths have been reported, people still suppose that the danger will not afflict them personally or that at least they will feel some ill-effect before they are overcome. But carbon monoxide gives no warning; its first effect is a sudden muscular weakness which renders the victim helpless. There should be a rule in large garages that no engine may be run for more than a very short time, for if this precaution is disregarded no amount of artificial ventilation will keep the air pure. In repair shops a flexible hose can be connected to the exhaust pipe of the car under repair so that the gas can be conducted out of doors.

Analyses of street air have shown that there is not really enough carbon monoxide in it to be poisonous, but there is certainly enough to join with the fumes of oil, dust, and smoke in contributing to the chronic fatigue of those who breathe this polluted air. It has been suggested that the vertical exhaust, if brought into general use on commercial vehicles and cabs, would considerably decrease the contamination of the air in congested traffic.

Treatment of Carbon Monoxide Poisoning.

The Committee is strongly in favour of inhalational treatment, because the asphyxia of carbon monoxide may continue in full force some time after the patient has been removed from the polluted atmosphere. If he is sent to hospital in an ambulance, he may well die on the way. Every minute of delay increases the chance of fatal injury to the brain, or at least of a subsequent pneumonia or damage to the heart. The carbon monoxide must be eliminated from the blood at the earliest possible moment. The victim should not be moved at all, or only for a few feet. Artificial respiration by the prone pressure method should be started without a moment's delay and continued until breathing returns or there is no doubt of the fact of death. So long as the victim is breathing, artificial respiration is undesirable, but inhalation of oxygen and carbon dioxide should be given at once or, if the mixture is not available, oxygen alone. While one helper sees to the artificial respiration, another should give the inhalation. Meanwhile the patient must be kept warm, and coats and blankets must be put under him as well as over him if he is lying on a cold surface. He should not be allowed to make any exertion until he is completely restored, as the heart may be badly strained thereby. The less the hypodermic syringe is used the better, and the practitioner is advised to leave the work of resuscitation to the specially trained rescue crews of the gas company and fire department if they are available. Transfusion of blood is quite useless though not actually harmful.

The inhalator generally used contains one or two cylinders of oxygen with which 7 per cent. of carbon dioxide has been mixed, and the Committee recommends that every ambulance should carry an apparatus of this kind. There are many advantages in using carbon dioxide as well as oxygen. An asphyxiated patient may not breathe enough oxygen to turn the carbon monoxide out of his blood. Oxygen is not a respiratory stimulant and may even be a depressant, and it is of little use alone where substances such as those of the benzene series have been inhaled as well as monoxide. Carbon dioxide restores full deep breathing, even in profound asphyxia, and displaces other poisonous gases besides carbon monoxide from the blood by inducing rapid ventilation. Moreover, full dilatation of the lungs after asphyxia tends to prevent subsequent pneumonia, which is otherwise common and has a high mortality. Carbon dioxide also rapidly restores the acid-base balance of the blood and tissues. The Committee states emphatically that pulmotors, lung motors, and other mechanical devices for artificial respiration should be replaced by general training in the prone-pressure method (Schafer).

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDING JAN. 25th, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 313 (last week 414); scarlet fever, 3225; diphtheria, 2033; enteric fever, 41; pneumonia, 1230; puerperal fever, 46; puerperal pyrexia, 139; cerebro-spinal fever, 11; acute poliomyelitis, 5; acute polio-encephalitis, 1; encephalitis lethargica, 14; continued fever, 1; dysentery, 9; ophthalmia neonatorum, 92. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Jan. 28th-29th was as follows:—Small-pox, 523 under treatment, 29 under observation (last week 528 and 18 respectively); scarlet fever, 2410; diphtheria, 2720; enteric fever, 19; measles, 954; whooping-cough, 119; puerperal fever, 34 (plus 18 babies); encephalitis lethargica, 121; poliomyelitis, 1; "other diseases," 17. At St. Margaret's Hospital there were 20 babies with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 3 (1) from enteric fever, 46 (22) from measles, 14 (2) from scarlet fever, 29 (3) from whooping-cough, 66 (12) from diphtheria, 39 (6) from diarrhœa and enteritis under two years, and 74 (16) from influenza. The figures in parentheses are those for London itself.

Small-pox was mentioned as a cause of death in a case assigned to Leicester (County Borough). The 2 fatal cases of enteric fever outside London were at Salford and Leeds. Measles accounted for 7 deaths in Manchester (where there were 738 fresh cases) and 3 in West Ham; whooping-cough for 6 in Birmingham and 3 each in Liverpool and Bradford. There were 12 deaths from diphtheria in Liverpool, 4 in Cardiff, and 3 each in Bristol, Birmingham, and Coventry. No great town had to report more than 4 deaths from influenza.

The number of stillbirths notified during the week was 295 (corresponding to a rate of 46 per 1000 births), including 53 in London.

DONATIONS AND BEQUESTS.—Mr. Frederick William Smith, of Woodville, Longridge, Lancs, left £1000 to Dr. F. W. Price, of Harley-street, London, to be applied as he shall think fit, for the benefit of the Heart Hospital, London.—Among other bequests, Mr. John Edward Faire, J.P., of Evington Hall, Leicester, left £5000 to the John Faire Hospital and £2000 to the Leicester and Leicestershire Maternity Hospital for general purposes.

Correspondence.

"Audi alteram partem."

MENTALITY AND ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—In a leading article in your issue of Jan. 25th (p. 193) you were good enough to refer to a paper written by me in the *British Journal of Anæsthesia*. In your kindly notice, however, you have missed, no doubt inadvertently, the main drift of my remarks. In an address I gave before the Royal Society of Medicine in 1920, entitled The Psychology of Anæsthesia, I drew attention to the neglected study of the subconscious side of patients requiring medical or surgical aid. I dwelt especially upon the effect of psychic influence in anæsthesia. The preponderating effects of buried brain-memories and the more recent profound impressions, such as the Great War brought into existence, were considered. The recent article, Mentality in Anæsthesia, was written as an extension and amplification of The Psychology of Anæsthesia. In it I advanced the contention that while most anæsthetists are careful to study and, indeed, to master the intricacies of the physical characteristics of their patients which might bring about unusual reactions of drugs used in anæsthesia, some do not, as a rule, study the psychical side of the problem and such study I submitted was at least as important.

Your reference to my article, however, appears to me to convey the inference that I devoted my remarks chiefly to the physical rather than to the psychical aspect of the problem. I trust that you will permit me, since I contend that the matter is really one of great importance, to correct this error and to point out that the subject of my paper is the psychical and not the physical side of anæsthesia. I am glad to learn that you attach importance to this subject and that the statements which appeared in my former paper find an echo in the concluding paragraphs of your article.

I am, Sir, yours faithfully,

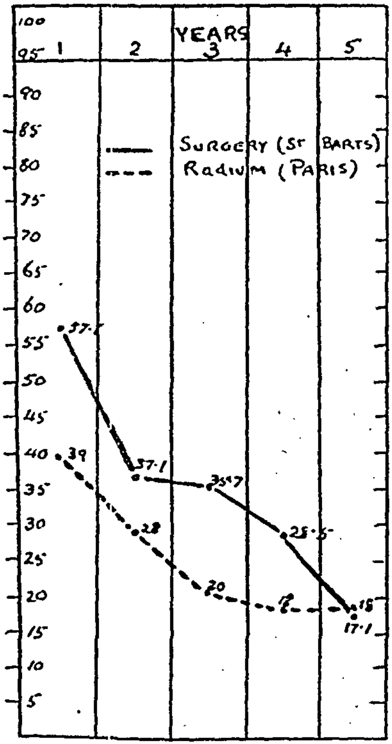
Boxmoor, Jan. 31st, 1930. DUDLEY W. BUXTON.

RADIUM OR EXCISION FOR EPITHELIOMA OF THE TONGUE

To the Editor of THE LANCET.

SIR,—Prof. Gask's admirable study of the treatment of epithelioma of the tongue by radium is of the greatest service at the present time when so many surgeons are trying out the new method. In striving to be fair to radium he is, however, a little less than fair to excision. Many of the figures he quoted are from old statistics. Since they were published the results which have been obtained, owing to improvements in anæsthesia, more extensive dissection of the glands, and the use of diathermic excision for the primary growth, are considerably better. Rendle Short reports 40 per cent. of three-year cures following the complete operation upon the tongue and glands at the Bristol Royal Infirmary.

Last year, for the purpose of the second edition of Recent Advances in Surgery, I had occasion to visit radium centres on the Continent, and to go into the available figures concerning the treatment by excision and by radium of cancers in various situations. The results in cancer of the tongue of operation by modern methods are probably much more fairly represented by the figure of 35·7 per cent. for three years obtained at St. Bartholomew's than by the 20 to 25 per cent. estimated by Prof. Gask. It is therefore hardly just, when referring to the 21·6 per cent. of three-year cures obtained in Paris by radium, to say that "this does not appear to be much better than the results of surgery." The Radiumhemmet figures he quotes give 14 cases alive out of 46 treated, a survival-rate of 30·4 per cent., but many of these had only recently been treated. The latest Stockholm figures in 1929 showed only 13 cases alive out of 71 treated over a period of six years, or an average of 18 per cent., and 5 of these 13 had been treated less than a year. Prof. Gask further remarks that if the period of observation is extended the percentage of cures by surgery would be further reduced. This is also true of cases treated by radium. The St. Bartholomew's surgical cases show 10 per cent. of seven-year cures, the Paris radium cases 11 per cent. The statement that if the primary growth be treated early (by radium) it can be made to disappear in the great majority of cases also needs qualification; in the cases treated by Regaud with radium the primary growth was not arrested in 56 per cent. In the accompanying graph I have added the curve of the Paris radium statistics, taken from Prof. Regaud's article in the American Journal of Roentgenology and Radium Therapy of January 1929, to that of Prof. Gask.



Epithelioma of tongue. Five-year survival rate of cases treated by surgery and by radium.

I do not wish in any way to belittle Prof. Gask's main thesis, which is admirable, or to decry the use of radium in cancer of the tongue, for I use it myself whenever possible. But if we are to advance we must face the truth, which is that at the present time, with the single exception of cancer of the lip, the results obtained by the best workers with radium are inferior to those obtained with excision by surgeons of equal standing. By careful research work, such as that carried on by the unit which Prof. Gask represents, the position may be reversed in the future. But that time has not yet come.

I am, Sir, yours faithfully,

W. H. OGILVIE.

Harley-street, W., Feb. 3rd, 1930.

PSITTACOSIS.

To the Editor of THE LANCET.

SIR,—Notices have already appeared in the press to the effect that a member of the female nursing staff of the Warwick County Mental Hospital is at present suffering from this condition. The following details are, I think, of interest. During December of last year friends of the patient, A.B., purchased in a public market a green parrot. On Jan. 9th of this year—that is, after about a fortnight—this bird died. Its dead body was taken back to the vendor, who supplied a new bird. This one was carried back to Warwick by train in a cardboard box by A.B., who herself, when she reached her friends' house, actually transferred the parrot from the box to its cage. Next morning the parrot was found dead in its cage. Two members of the family were taken ill on Jan. 12th, and the third on the 19th. Besides actually handling the parrot in question A.B. had subsequently helped to nurse her ill friends on Jan. 15th. One of these died later.

A.B. herself first noticed symptoms on Jan. 19th. They were fever, nausea, vomiting, and backache. She did not report sick to us until Jan. 22nd, when she had all the symptoms above noted, an extremely dirty brown-coated tongue, a temperature of 104·0° F., and she looked very seriously ill. On Jan. 22nd a blood culture was done which turned out to be sterile. The leucocyte count was 20,400. Agglutination with standard Oxford cultures of *B. typhosus*, *B. paratyphosus* A, *B. paratyphosus* B, *B. ent.* Gaertner, gave negative results down to dilutions of 1 in 25. A dry, troublesome, cough started about Jan. 25th and there are small areas of consolidation in the lungs to account for this. The course of her case has been a steady constant temperature round about 103°F. for the first week, gradually coming down and the symptoms moderating more or less accordingly. The temperature actually touched normal for the first time on Feb. 1st, and is at the present time in the neighbourhood of 100°F. She still has feelings of nausea but the lung signs are clearing up and the patient's condition steadily improving. There has never been any splenic enlargement. On Jan. 25th the leucocyte count was 17,200 and on the 28th was 10,800 (polymorphs, 63 per cent.; lymphocytes, 35 per cent.; transitional, 2 per cent.). On the same day agglutination against the same four organisms mentioned above was again negative. The urine was sterile. No non-lactose-fermenting colonies were found on plates from the stools. On blood culture after 48 hours a growth was obtained in broth of a Gram-negative motile bacillus. Subcultured, this bacillus grew readily and copiously in 24 hours on an ordinary agar slope. It was markedly hæmolytic. It would not ferment glucose, lactose, saccharose, maltose, or mannite. Litmus milk remained alkaline after 24 hours, turning slowly acid after 48. There was no clotting. So far subcultures made each day have remained true to the above type except that the power to turn the litmus red is getting weaker. On Feb. 2nd the leucocyte count was 6100. An organism with apparently the same characteristics was grown from the urine.

I am, Sir, yours faithfully,

A. T. W. FORRESTER,
Medical Superintendent, Warwick County Mental Hospital.
Feb. 3rd, 1930.

SPINAL ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—I offer Dr. Falkner Hill an apology for misinterpretating him. The explanation of the escape of the phrenic motor roots when numbness in the neck follows a novocain injection, is, I believe, simple.

(1) The upper remnant of a heavy solution tends to affect the posterior roots more than the anterior.

(2) The concentration in the cervical region is too dilute to affect motor fibres.

If a small dose of novocain is injected across the cauda equina between L1–L2, pain sense in the leg is the first to go, then follow touch, muscular sense, and finally motor power. Return is in the reverse order, and an operation on the leg may continue after muscular control has returned. Motor fibres are more resistant and recover more easily than sensory. When after an injection a man is unable by voluntary effort to move his leg, the motor path is blocked as well as the sensory. During the recovery he can stimulate his muscles at will, but the afferent pain path remains blocked. Could this sequence be explained by receptor paralysis alone?

In the dorsal region, Dr. Falkner Hill can find no stimulus for the abdominal muscles, assuming that the efferent path becomes unlocked before the afferent. Are they not part of the normal respiratory mechanism, and do they not receive central stimuli? Failure to get a sufficient concentration of novocain on the anterior roots from D6 down accounts for statements that novocain does not give good relaxation and the early return of rigidity in the upper abdomen is but the natural consequence of a diminishing concentration of novocain from below upwards. The following case is instructive.

> Percain normal saline S.G. 1.006. Profound splanchnic block. Man, aged 62, carcinoma of the colon. Resection of terminal portion of ileum, cæcum, and part of ascending colon; lateral anastomosis. At 1 hour 15 minutes during the anastomosis patient complained of pain in the stomach, which persisted until its completion. With a novocain administration this pain would have been preceded by increasing rigidity, later accentuated by painful stimuli. But not so in this case; 20 minutes after pain was first felt the abdominal wall was perfectly relaxed, and was sewn up without the slightest difficulty. The receptors had recovered, but the motor mechanism was unable to respond. The solution was evidently lighter than the cerebro-spinal fluid, and had applied itself more to the anterior roots than to the posterior.

The contrast between the behaviour of these two types of solutions seems to provide some evidence that the roots are the site of the block.

Dr. Falkner Hill, criticising the controllability of *spinocain asks, "If expansion is essential for a high* anæsthesia, how is it that a high and long anæsthesia is produced when only 2 c.cm. of cerebro-spinal fluid have been extracted?" I would add to this, especially if "gliadin holds the solution together." I find that in order to pass the roots of D5 I must make a direct injection of between 15 and 20 c.cm. of solution between L1–L2. Can it be possible that after all spinocain is, or behaves in the same manner as a heavy solution? If 2 c.cm. of spinocain were quietly injected between L1–L2 without "expansion," would there be no advance on the thoracic nerve roots in the Trendelenburg position?

Dr. Falkner Hill writes: "Though this quality of lightness may be of no physical importance, in the present state of opinion it has a very definite psychological value." I have always regarded spinocain as a great achievement in practical psychology.

I am, Sir, yours faithfully,

London, W., Feb. 3rd, 1930. W. HOWARD JONES.

MENTAL TREATMENT BILL.

To the Editor of THE LANCET.

SIR,—In your issue of Feb. 1st (p. 263) Dr. S. E. White, commenting on a leading article dealing with amendment of the Lunacy Acts, states that—

> As regards transient cases of high temperature with delirium (e.g., puerperal, pneumonic, influenzal) it is very undesirable to treat such cases in asylums because there is there no qualified nursing staff competent to take charge of patients in such peril of their lives.

As one who has had 24 years' experience of mental hospitals I feel that I cannot allow such a statement to go uncontradicted. The statement is in fact so far removed from the truth that one can only conclude that Dr. White has no real knowledge or experience of what she is talking about. She is evidently ignorant of the fact that nurses in mental hospitals who enter for the mental section of the General Nursing Council's examination sit exactly the same preliminary examination as the general hospital nurse. She is also probably ignorant of the fact that facilities exist whereby the nurse who has passed the G.N.C. examination in the mental section can obtain her " general " certificate by two years further training at a general hospital, and that in the Devon Mental Hospital alone no less than five have already shown enough enthusiasm to take this extra course, and so become " doubly qualified."

But apart from this, cases of delirium are so commonplace in mental hospitals that it is absurd to allege that " asylum nurses " are incompetent to deal with them. A " certificated mental nurse " is in my opinion the best possible nurse to attend cases of delirium. She has at least been given special instruction in the psychological aspect of such conditions to which her sister in the general hospital pays little attention. The keenness shown by the mental hospital nurse in this way deserves praise and encouragement.—I am, Sir, yours faithfully,

RICHARD EAGER, O.B.E., M.D.,
Medical Superintendent, Devon Mental Hospital, Exminster.
Feb. 2nd, 1930.

THE CLAIMS OF LOURDES

To the Editor of THE LANCET.

SIR,—On page 196 of THE LANCET of Jan. 25th there appears an annotation headed " Austrian Thaumaturgist." One sentence in this article must have caused much astonishment and disgust in the minds of many of your readers. The sentence reads " the place is in fact a veritable Lourdes, which it resembles in the nature of the diseases cured, which are mainly of a neurotic type with a sprinkling of rheumatic and pseudo-paralytic affections."

I have rarely seen a short sentence which contains so many mis-statements, to use a mild term. I might ask in what possible way does the clinic of this thaumaturgist resemble the shrine of Our Lady of Lourdes, where pilgrims flock in scores of thousands to implore the intercession of the Blessed Virgin for the cure of their spiritual and corporal ills. Then, again, the remainder of the sentence is an absolute travesty of truth. The Bureau de Constatations Médicales at Lourdes is open to any medical man be his religious opinions what they may. These gentlemen are invited to examine and report on all cases claiming to be miraculous cures. Only after a thorough investigation and after the lapse of 12 months is a definite opinion passed on the fact of a miracle having occurred. Perhaps the most surprisingly inaccurate of all the statements contained in this marvellous sentence is that the majority of the cases cured at Lourdes are of the neurotic type, &c. It will perhaps amaze the author of this extraordinary statement to know that such cases are never claimed as miracles or are recorded as such by the Bureau at Lourdes.

In conclusion, I may say that, as a constant reader of your valuable periodical, I am astonished at the action of the Editor of THE LANCET in allowing such a travesty of truth to appear in a scientific journal.

I am, Sir, yours faithfully,
J. B. MOORE, M.B., F.R.C.S.I.
Belfast, Jan. 29th, 1930.

MEDICINES IN THE MASS.

To the Editor of THE LANCET.

SIR,—Your leading article on Medicines in the Mass reminds me that I once saw a patient who took so much medicine that the chemist called every day for orders.—I am, Sir, yours faithfully,

Jan. 29th, 1930. W. HALE-WHITE.

Parliamentary Intelligence.

HOUSE OF COMMONS

WEDNESDAY, JAN. 29TH.

Amendment of the Children Act, 1908.

Sir ROBERT GOWER asked the Minister of Health whether he was aware that the Medway board of guardians had passed a resolution urging His Majesty's Government to initiate legislation amending Part I. of the Children's Act, 1908, to the effect that it should be made compulsory upon intending foster parents to apply to the local authority concerned for the registration of their premises for the reception of nurse infants before the reception actually takes place; and whether he proposed to introduce such amending legislation.—Mr. GREENWOOD replied: The answer to the first part of the question is in the affirmative. This suggestion will receive consideration in connexion with any legislation for the amendment of the Children's Act, 1908, but I cannot give any date for the introduction of such legislation.

Air-gun Accidents among Children.

Mr. FREEMAN asked the Home Secretary whether, in view of the number of accidents from air-guns amongst small children, he would consider the desirability of limiting their use to the holders of a duly issued licence.—Mr. CLYNES replied: If the mischiefs to which the Firearms Act, 1920, was directed by Parliament were found to arise as regards air-guns, power already exists to impose the requirement of a firearm certificate, but those mischiefs do not arise, and I do not think sufficient ground exists for proposing legislation to set up a licensing system with other objects in view.

Naval Officers' Photographs.

Sir NICHOLAS GRATTAN-DOYLE asked the First Lord of the Admiralty whether, with regard to the instructions recently issued requiring all officers at certain stages of their naval careers to submit photographs of themselves to the Admiralty, he would state for what purposes those photographs were required; and at what stages of their naval careers officers had to submit them.—Mr. ALEXANDER replied that, so far as medical officers were concerned, the answer was: on entry and on promotion to surgeon-commander. Dental officers were required to submit photographs on entry and on attaining six years seniority as surgeon lieutenant-commander (D).

THURSDAY, JAN. 30TH.

Diagnosis of Silicosis.

Mr. CECIL WILSON asked the Home Secretary whether any and, if so, which of the recommendations of the departmental committee on the diagnosis of silicosis were to be adopted; and when it was anticipated that the central bureau would be set up.—Mr. CLYNES replied: I have approved generally the medical arrangements recommended by this committee, but I am advised that they cannot be given effect to without further legislation and a Bill is accordingly in preparation. I have already acted on the recommendation of the committee in favour of further research by arranging with the Medical Research Council for the appointment of an expert committee.

Fibrosis of the Lungs and Workman's Compensation.

Mr. MORLEY asked the Home Secretary what further steps had been taken towards scheduling fibrosis of the lungs under the Workmen's Compensation Act.—Mr. CLYNES replied: This is a big question on which I was advised that much further research would be necessary, and I therefore asked the Medical Research Council to set up an expert committee to institute and coördinate research into the subject. I am glad to say that the Council have agreed to do this, and are now engaged in setting up a committee. I understand that the committee is practically complete and will be appointed very shortly.

Defective Schools.

Mr. KINLEY asked the President of the Board of Education the number of voluntary schools listed as defective, or no longer suitable; and the number of children in average attendance at those schools.—Sir CHARLES TREVELYAN replied: The total number of voluntary schools remaining on the black list is 1323. The total number of children on the registers of these schools on March 31st last was 318,892.

Ministry of Health and Meat Extracts.

Mr. FREEMAN asked the Minister of Health whether his attention had been called to an advertisement appearing in many newspapers, and particularly on Saturday, Dec. 28th, 1929, in an evening paper, implying that the Health Ministry recommended certain meat extracts; whether the recommendation was given; and, if not, what action he proposed to take in the matter to dissociate the Ministry from such advertisements.—Mr. Greenwood replied: The answer to the first part of the question is in the affirmative. My department does not recommend this or any other meat extract. But the advertisement does not appear to contain any mis-statement of fact in regard to the Ministry of Health, and while I deprecate such a form of advertisement, I do not think that I can usefully take any action in the matter.

Psittacosis in Birmingham.

Mr. Hannon asked the Minister of Health whether his attention had been called to a recent statement by the medical officer of health for Birmingham that several cases of psittacosis, definitely caused by infection from parrots, had occurred in Birmingham within the past two years; and, seeing that of 11 cases reported in Birmingham during the period stated four had proved fatal, he would say what steps the Ministry had taken to deal with this malady.—Mr. Greenwood replied: I am informed that the medical officer of health of Birmingham has not made any public statement of the kind referred to. As regards the second part of the question, I would refer the hon. Member to the answer given on Jan. 23rd[1] to the hon. and gallant Member for Warwick and Leamington.

Mr. Hannon: Has the right hon. gentleman any information from Birmingham of the result of the inquiry which he has ordered to be made, and can he give any information as to what practical steps are being taken to put an end to this malady?

Mr. Greenwood: As I explained to the House, investigations are not complete.

Dr. Davies: Is the right hon. gentleman aware that both Germany and the United States have prohibited——

The Speaker: The hon. gentleman is giving information.

Birth Control.

Mr. Morley asked the Minister of Health how many local authorities had desired him to give consideration to the question of allowing municipalities to provide facilities for reliable and private information as to the methods of family limitation.—Mr. Greenwood: Fifty-five.

Mr. Morley: Will the right hon. gentleman inform the House if and when he is prepared to grant these facilities?

No answer was given.

Vaccination Exemptions.

Mr. Thomas Lewis asked the Minister of Health the number of children exempted from vaccination on conscientious grounds during 1929.—Mr. Greenwood replied: The number of statutory declarations of conscientious objection received by the vaccination officers in England and Wales during the calendar year 1928 was 277,169. The figure for 1929 is not yet available.

Extension of National Insurance.

Mr. George Oliver asked the Minister of Health whether it was the intention of the Cabinet committee charged to inquire into the subject of national insurance and pensions to consider the extending of insurance to persons who, by reason of occupation or income, were excluded from the present schemes of insurance.—Mr. Greenwood replied: The question referred to by the hon. Member will be considered by the Cabinet committee.

Medical Practitioners and Death Certification.

Sir George Penny asked the Minister of Health whether he would take steps to make it obligatory upon a medical practitioner to view a body after death before giving a death certificate.—Mr. Greenwood replied: This subject was fully discussed during the passage through this House of the Births and Deaths Registration Act of 1926; and I am not prepared to introduce further legislation in present circumstances.

Leprosy in India.

Major Graham Pole asked the Secretary of State for India the number of known cases of leprosy in India, and how many of these were segregated either in their homes or in institutions; whether the Government took any steps to effect their compulsory segregation either in their homes or in institutions; and what was the number of leper institutions in India and the total amount contributed out of Indian revenues towards the extinction of this disease.—Mr. Wedgwood Benn replied: The number of persons in India returned as lepers at the census of 1921, the last official figure available, was 102,513, but it is probable that the number is considerably in excess of that returned. There are about 40 institutions with about 8000 inmates. The Indian Lepers Act provides that the compulsory segregation of pauper lepers may be enforced in areas to which the Act is made applicable by the provincial governments, but the total number of compulsorily segregated lepers is at present inconsiderable. The number of lepers segregated in their homes, and the total amount contributed from Indian revenues cannot be stated.

The following note has been supplied by Sir Leonard Rogers: "Any attempt at general compulsory segregation is impossible on account of the prohibitive cost, and now that the improved treatment enables most early, but few advanced, cases to be cleared up, compulsion does more harm than good by causing the early, largely uninfective, cases to be hidden until they have become advanced, infectious, and incurable. At the present time about one hundred doctors are being trained in the modern treatment at the Calcutta School of Tropical Medicine, and thousands of lepers are now being treated by them all over India at clinics with far greater effect in reducing leprosy than attempts at segregation, which have invariably proved very expensive failures in all tropical countries where they have been tried."

MONDAY, FEB. 3RD.

All-India Medical Council.

Major Graham Pole asked the Secretary of State for India if it was the intention of the Government to take early steps towards the establishment of an all-India medical council.—Mr. Wedgwood Benn replied: The Government of India are anxious to introduce the necessary legislation at the earliest possible date, but it is doubtful whether this will be possible during the present session of their Legislature.

Lieut.-Colonel Fremantle asked the right hon. gentleman to do his utmost to impress on the Government of India that, unless there was reciprocity between the two Governments and the two medical councils, Indian practitioners would be debarred from the possibility of practice throughout the rest of the British Empire; and that it was therefore extremely important to keep the General Medical Council and the Council in India working together.—Mr. Benn replied that the Government of India were fully aware of the facts mentioned by Colonel Fremantle.

Central Research Institute in India.

Major Graham Pole asked the Secretary of State for India the intention of the Government of India towards the proposal to remove the Central Research Institute to Dehra Dun, in view of the fact that there would be an absence of the clinical facilities and the scientific coöperation available in larger urban areas.—Mr. Wedgwood Benn replied: The Government of India have decided after full consideration to adhere to the proposal to locate the Institute at Dehra Dun. Their reasons were explained in the course of a debate in the Council of State on Sept. 17th.

Small-pox Deaths in India.

Mr. Freeman asked the Secretary of State for India how many small-pox deaths were registered in each of the cities of Calcutta, Bombay, and Madras in the years 1925, 1926, 1927, and 1928, respectively; and what was the infant mortality-rate in each city for the same years.—Mr. Wedgwood Benn replied: The following tabular statement contains the figures:—

—	Small-pox deaths.				Infant mortality death-rate per 1000.			
	1925	1926	1927	1928	1925	1926	1927	1928
Calcutta ..	3923	934	2860	N.r.	326	372	340	N.r.
Bombay ..	565	476	841	595	359	394	319	314
Madras ..	762	60	32	246	281	282	240	289

N.r.—Not yet received.

Local Government Act, 1929.

Mr. West asked the Minister of Health whether he had received any representations from the Metropolitan Boroughs Standing Joint Committe with reference to the scheme which he proposed to make, under Section 101 (6) of the Local Government Act, 1929; and whether he was satisfied that under that Act he was authorised to confer on the London County Council the supervisory powers over certain voluntary associations which were specified in paragraph 3 of the proposed scheme.—Miss S. Lawrence replied: The answer to both parts of the question is in the affirmative.

TUESDAY, FEB. 4TH.

After-care of Mental and Physical Defectives.

Dr. Forgan asked the Secretary of State for Scotland if, in view of the value of the work being carried out in Scotland by after-care committees in connexion with mental and physical defectives, he would consider the advisability of increasing the average annual Government grant of £18 to removed from the truth that one can only conclude that Dr. White has no real knowledge or experience of what she is talking about. She is evidently ignorant of the fact that nurses in mental hospitals who enter for the mental section of the General Nursing Council's examination sit exactly the same preliminary examination as the general hospital nurse. She is also probably ignorant of the fact that facilities exist whereby the nurse who has passed the G.N.C. examination in the mental section can obtain her "general" certificate by two years further training at a general hospital, and that in the Devon Mental Hospital alone no less than five have already shown enough enthusiasm to take this extra course, and so become "doubly qualified."

Ministry of Health and Meat Extracts.

Mr. FREEMAN asked the Minister of Health whether his attention had been called to an advertisement appearing in many newspapers, and particularly on Saturday, Dec. 28th, 1929, in an evening paper, implying that the Health Ministry

Univ. Coll.; Alison J. Rae, Royal Free; D. S. Raju, Madras and Guy's; H. Ramsay, Middlesex; P. V. Reading, Guy's; J. G. Reid, Oxford and St. George's; B. C. Rennie, Otago; Colleen Rice, Charing Cross; J. F. Riches, St. Thomas's; E. H. Rink, Oxford and Guy's; S. L. Robert, Bombay and Birmingham; B. P. Robinson, Manchester; Alice I. Roughton, Cambridge; H. K. Said, Cairo and Charing Cross; J. F. Sandow, Middlesex; N. D. Sane, Bombay and London: S. Segalov, St. Bart.'s; R. L. Sethi and D. P. Settna, Bombay and London; G. C. Sheldon, King's Coll.; Helana Sidarous, Royal Free; H. Silverstein, St. Bart.'s; Margaret Skelton, Univ. Coll.; L. A. H. Snowball, King's Coll.; R. G. Sowter, Guy's; H. H. L. Spitz, Leipzig and Middlesex; B. T. Squires, Oxford and Guy's; R. Stanley, Birmingham and St. Thomas's; A. E. Stevens, London; E. N. Stevens, Guy's; N. Stevens, Cambridge and St. Thomas's; F. H. Stevenson, Guy's; Ada M. W. Stewart, Liverpool and Univ. Coll.; T. S. Stone, London; S. Le R. Switzer, Cambridge and London; P. H. Taylor, King's Coll.; D. M. Thomas, Middlesex and Cardiff; V. Thorne Thorne, Cambridge and St. Bart.'s; D. P. Turner, King's Coll.; S. C. Wake, Bristol; Doris E. C. Walker, Univ. Coll.; E. M. Ward, St. Bart.'s; J. N. Warren, Cambridge and London; A. J. Whitaker, Univ. Coll.; A. J. White, Middlesex: G. W. Whittall, Cambridge and St. Thomas's; R. C. Williams, St. Thomas's; E. R. Willis, London; H. M. Yardley, Cambridge and St. Thomas's; and B. Yuill, Toronto and London.

The undermentioned diplomas were conferred jointly with the Royal College of Surgeons upon the following candidates:—

DIPLOMA IN PUBLIC HEALTH.

D. D. Anderson, S. Atta Ullah, B. N. V. Bailey, M. K. Biswas, Gwenddolen J. Brooke, Izza Caley, H. D. Chalke, Victoria M. Crosse, Jane G. E-F. Cummins, N. C. Dasgupta, A. N. Duggal, J. B. Ellison, R. F. Fidler, S. J. Firth, Annie M. Gamble, T. S. Gill, S. A. Haque, L. W. Hearn, G. H. Hogben, J. D. Hourihane, D. F. Johnstone, M. L. Kalra, Y. M. Khan, R. A. V. Lewys-Lloyd, E. A. Lumley, R. M. Macfarlane, M. Mitman, S. K. Mitra, P. McG. Moffatt, C. G. M. Nicol, P. Pattabhiramaiya, J. R. Pierre, S. L. Rikhye, Dora F. M. Rose, A. C. Sinclair, E. R. Smithard, R. C. Suri, H. W. Tilling, P. M. Wagle, and Ethel M. Weir.

DIPLOMA IN LARYNGOLOGY AND OTOLOGY.

W. M. Brown, S. Debono, D. N. Ghosh, G. B. Girgis, S. K. Jatar, V. Kathirgamatamby, J. G. Kingsbury, F. E. Littlewood, M. MacGregor, N. M. Macindoe, H. G. Mitchell, J. H. Otty, M. D. Patel, D. R. Paterson, P. Pattabhiramaiya, T. Prasad, D. H. Rao, and S. L. Vella.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.

D. I. Cameron, J. Carse, H. A. Cooper, R. T. Hay, J. F. MacMahon, J. D. W. Pearce, Margaret A. Quine, A. Shepherd, J. G. T. Thomas, G. S. Wilson, and H. L. Wilson.

UNIVERSITY OF LONDON.—At a meeting of the Senate on Jan. 29th the degree of D.Sc. in Zoology was awarded to Mr. E. A. Spaul for a thesis on the Activity of the Anterior Lobe Pituitary.

Dr. H. A. Harris, assistant professor of anatomy at University College; and assistant to the medical unit at University College Hospital, was awarded the William Julius Mickle Fellowship for 1930 in respect of research on problems of growth in man and animals. This Fellowship is given annually to the graduate of the University who is held to have done most to advance medical art or science in the preceding five years.

Mr. H. L. Eason was reappointed representative of the University on the General Medical Council.

A Diploma in Public Health for External Students was established.

University College.—A course of six public lectures on Antiseptics will be given by Mr. H. R. Ing, D.Phil., on Mondays and Thursdays at 5.15 P.M., beginning on Feb. 13th.

ASSOCIATION OF CLINICAL PATHOLOGISTS.—The third annual meeting of the British Pathologists' Association was held in the Pathological Department, University College Hospital Medical School, on Jan. 26th. The morning session was devoted to the consideration of the Technique and Interpretation of the Fractional Test Meal. Communications were made by Dr. E. Christine Emma Pillman-Williams, who described the technique of the withdrawal and analysis of the meal, and by Dr. G. W. Goodhart, who dealt at length with the interpretation of results. Dr. Goodhart laid special stress upon the importance of the determination of the chlorides, and expressed the opinion that the findings could best be accounted for on the assumption of regurgitation of alkaline duodenal contents. Both papers were followed by lively discussion. During the afternoon session demonstrations were given as follows: by Dr. H. D. Wright, medium for growing pneumococci; hæmolytic power of streptococci. Dr. G. W. Goodhart, diphtheria of the vulva; pernicious anæmia without achlorhydria. Dr. D. Embleton, blood from recovered case of agranulocytic angina. Dr. G. W. Barnard, hearts injected to show the coronary circulation; hearts showing coronary thrombosis. Prof. Hadfield, specimens from case of Lindau's disease, and other pathological specimens. At the general meeting it was decided to change the name of the association to the Association of Clinical Pathologists.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—A provincial meeting of the maternity and child welfare group will be held at Bristol from Feb. 20th to 22nd. The hon. secretary's address is 1, Holly-terrace, Highgate, London, N. 6.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION.—The annual general meeting of this association will be held at 11, Chandos-street, Cavendish-square, London, W., on Friday, Feb. 21st, at 5 P.M., when Dr. G. E. Friend will deliver a presidential address, entitled Some Notes on the Value of Clinical, Dietetic, and Physical Records in Public Schools.

POST-GRADUATE COURSE IN ORTHOPÆDIC SURGERY.—A special fortnight's course will be held at the Royal National Orthopædic Hospital, Great Portland-street, London, W. 1, from March 10th to 22nd. Those taking the course will have access to operations and the practice of the hospital. Application should be made to the secretary of the hospital, or to the secretary of the Fellowship of Medicine, at 1, Wimpole-street, W.1.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY.—A dinner in honour of Dr. Heinrich Neumann, professor of otology in the University of Vienna, will be given by this society at the First Avenue Hotel, High Holborn, London, on Sunday, Feb. 9th, at 7.15 for 8 P.M. Application should be made to Mr. M. Sourasky at 59, Queen Anne-street, W.1.

INTERNATIONAL SOCIETY FOR MICROBIOLOGY.—The first international Congress organised by this society will be held in Paris from July 20th to 25th. Those who desire to take part, whether members of the society or not, should send a subscription of 100 French francs to the Treasurer of the Congress, M. Georges Masson, 120, Boulevard Saint-Germain, Paris (VI^e). Notification for enrolment will be received up to June 15th.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL.—The committee of management has decided to appoint a pædiatrician to the staff of this hospital, and Dr. Eric Pritchard has, at their invitation, accepted this office. It is understood that this appointment will not conflict with Dr. Pritchard's work as Medical Director of the Infants Hospital. Dr. J. Hartley Gibbens has been appointed assistant to Dr. Pritchard at Queen Charlotte's.

ANIMAL DISEASES RESEARCH INSTITUTE.—Mr. John Russell Greig, Ph.D., professor of medicine and materia medica in the Royal (Dick) Veterinary College, Edinburgh, has been appointed Director of the Institute at Moredun in succession to Mr. W. A. Pool, who is now Deputy Director of the Imperial Bureau of Animal Health at Weybridge.

NEW NURSES' HOMES.—The new nurses' home at Crumpsall Infirmary, Manchester, was formally opened last week by Mr. Hugh Fay, Chairman of the Manchester Board of Guardians. The building, which has cost £80,000, will accommodate 220 nurses.—A home for the nurses of Forfar Infirmary, built with an allocation from the estate of the late Sir James Duncan, was also opened last week.

SUN-BATHING IN MANCHESTER.—The Manchester Parks Committee have decided that Platt Fields should be the first park in which sun-bathing may be combined with open-air bathing. The necessary alterations will be made so that sun-bathing may be begun at the end of May (weather permitting). People will be able to go to Platt Fields and take sun-baths on the sand in bathing costumes.

REDLANDS HOSPITAL FOR WOMEN.—This Glasgow hospital has just been enlarged by the incorporation of an adjoining house which will accommodate 22 maternity cases. The object of the maternity extension is to provide efficient treatment for expectant mothers able to pay a fee ranging from 3½ to 6 guineas a week.

ADDENBROOKE'S APPEAL.—Last week Sir Humphry Rolleston broadcast an appeal from 5XX for the building fund of Addenbrooke's Hospital, Cambridge. He stated that of the £90,000 required only about one-third had yet been raised.

LERWICK HOSPITAL.—It is hoped to raise £10,000 to enlarge and a further £10,000 to endow the Lerwick Hospital which serves the Shetland Islands. Last year there were 339 in-patients and 882 out-patients, the operations numbered 481, and the percentage of deaths was 4·39.

DUNFERMLINE AND WEST FIFE HOSPITAL.—The Managers report that the cost per occupied bed had increased last year from £98 9s. 4d. to £103 17s. 6d.; there was a surplus on the year's working of £2628. An important extension, for which over £51,000 has been raised, will be ready for occupation at the beginning of next month.

London Clinic for Rheumatism.—On Feb. 25th the Queen will open the new clinic for the treatment of rheumatism which is being established by the British Red Cross Society in Regent's Park, London. It is stated that the clinic will be capable of dealing with 400 cases a day. It will provide treatment: (1) for workers insured under the National Health Insurance Acts, and (2) for men and women able and willing to pay a reasonable fee. There will be a resident medical officer and a visiting staff of physicians and surgeons.

Dinner to Nobel Laureates.—Sir Charles Martin presided at a dinner given in London by the Biochemical Society on Feb. 3rd in honour of the Nobel Laureates in Chemistry and Medicine for the past year. Sir Frederick Hopkins, Prof. Hans von Euler, and Prof. Arthur Harden responded briefly to the toast proposed by the chairman, and seconded by Prof. G. Barger. The fourth Laureate, Prof. C. Eijkman, was unable to be present owing to ill-health. The Swedish Minister and the President of the Royal Society responded to the toast of the Guests, proposed by Sir William Hardy.

Royal Medical Benevolent Fund.—At meetings of the Committee in December and January a total of £2379 was voted in 113 cases in which help was required by medical men or by their widows or families. The following are particulars of five of these cases:—

Widow, aged 50, of L.R.C.P.&.S. whose husband died suddenly in September, 1929, at the age of 51 from heart failure. The widow who is in very delicate health was left an income of £50 p.a. and children dependent on her. Voted Grant of £36 and a special gift of £14.

M.D., aged 60, married, suffering from tuberculosis and in a Sanatorium. Practice has been sold and when proceeds are invested will give an income of £135. Applicant has one son and two daughters. Two eldest have secured posts. Voted £40.

Widow, aged 60, of M.R.C.S. Her husband suffered from ill-health all his life and was never able to work enough to save any money. At his death in November the widow and one daughter were left with a capital of £200. The daughter has been trained and will obtain employment. Voted £26 and special gift of £10.

Two daughters, aged 61 and 58, of L.F.P.S. Only income is £17 each, gifts from friends and deposit interest on the sum of £57. Voted £36 each.

Daughter, aged 70, of M.R.C.S. Has been in bed during the whole of the last 12 months. Income from charities £30; old age Pension £26. Voted £30.

The Committee appeals urgently for subscriptions, donations, and legacies. Cheques should be sent to the hon. treasurer of the Fund at 11, Chandos-street, W.1.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, Feb. 10th.—5 p.m., United Services (late War Section). Paper: Wing.-Comdr. H. A. Treadgold: Cardiac Functional Efficiency in the Young Male Adult.

Tuesday.—5 p.m., Therapeutics and Pharmacology. An informal Discussion on the Treatment of Uræmia. Opener: Prof. F. Langmead. Members of the Sections of Urology, Medicine, and Disease in Children are specially invited to attend and take part in the Discussion. 8.30 p.m., Psychiatry and Neurology. Discussion on the Diagnosis and Treatment of the Milder Forms of the Manic-depressive Psychosis. Openers: Sir Farquhar Buzzard, Dr. George Riddoch, Dr. W. R. Reynell, and Dr. Neill Hobhouse (Neurology, Dr. Crichton Miller, Dr. Maurice Wright, and Dr. Helen Boyle (Psychiatry).

Wednesday.—5.30 p.m., Surgery: Subsection of Proctology. Discussion on Factors Making for Safety in the Surgery of the Colon and Rectum. Opener: Mr. G. Gordon-Taylor. Followed by Sir Charles Gordon-Watson, Mr. Ivor Back, Mr. Lionel Norbury, Mr. W. B. Gabriel, Mr. Lawrence Abel, and others.

Thursday.—8.30 p.m., Neurology. Short Papers: Dr. S. A. K. Wilson: The Relation of Nervous Symptoms to Nervous Lesions. Dr. E. Arnold Carmichael and Mr. J. Paterson Ross: Radium and Nervous Tissue; an Experimental Study.

Friday.—5.30 p.m., Clinical. *(Cases at 4.30 p.m.). Cases:* Mr. Philip Turner: 1. A Case of Von Recklinghausen's Disease. Mr. Cecil P. G. Wakeley: 2. Case of Fracture of Cervical Spine. 3. Case of Dislocation of the Carpal Semilunar. 4. Köhler's Disease with "Mulberry" Femoral Epiphyses. 5. Tuberculous Ulcer of Tongue. Dr. Bernard Myers: 6, 7 and 8. Three Cases of Purpura. 9. Case of Spina Bifida. Mr. Paul Bernard Roth: 10. Unusual Case of Loose Body in Each Knee-joint of Traumatic Origin. Dr. F. Parkes Weber and Dr. O. B. Bode: 11. Facial Lipodystrophia with Unerupted Upper Central Incisor Teeth. 12. Alopecia Totalis after Slight Nervous Shock. Mr. Harold Edwards: 13. Case of Cutaneous Growth of Keloid Nature (for Diagnosis). 14. Cyst of the Neck of the Femur in a Child. Mr. R. Rutherford: 15. Case of Schlatter's Disease. 16 and 17. Two Cases of Multiple Exostoses in a Family. Dr. Harold Avery: 18. A Case of the Jaw-winking Reflex. 19. Case of Rumination in Man. 20. Advanced Osteo-arthropathy in a Case of Pulmonary Neoplasm. Mr. A. E. Mortimer-Woolf: 21. Case of Osteitis Deformans with Sarcoma. Dr. Terence East: 22. Case of Splenic Enlargement of Obscure Origin. 8 p.m., Ophthalmology. Papers: Mr. Foster Moore: Unusual Coloration of Sclerotics. Mr. Ransom Pickard: The Red Field and Optic Disc Resistance in Glaucoma and Allied Conditions. Cases: Mr. J. H. Doggart: A Case of Distichiasis. Mr. A. F. MacCallan: Binocular Detachment of Retina in a Boy Aged 8. Other Cases will be shown.

BIOCHEMICAL SOCIETY.

Monday, Feb. 10th.—3.30 p.m. (at the Lister Institute, Chelsea Bridge-road, S.W.). Demonstrations. Papers *at 5 p.m.*

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

Friday, Feb. 14th.—4 p.m., Prof. E. W. Hey Groves: Hero Worship in Surgery. (Hunterian Oration.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, Feb. 10th, to Saturday, Feb. 15th.—Medical Society (Lecture Room), 11, Chandos-street, Cavendish-square, W. Tues., at 4 p.m., Lecture by Dr. M. B. Ray on the Rôle of Hydrology in Medical Practice. No fee.—Cancer Hospital, Fulham-road, S.W. Thurs., at 2.15 p.m., Demonstration by Mr. Cecil Rowntree. No fee.—Paddington Green Children's Hospital, Paddington Green, W. Fri., at 4 p.m., Lecture-demonstration by Dr. D. W. Winnicott on Anxiety in Children. No fee.—Chelsea Hospital for Women, Arthur-street, S.W. Special course in Gynæcology, lectures and demonstrations in the operating theatre.—Hospital for Tropical Diseases, 25, Gordon-street, W.C. Post-graduate course in Tropical Medicine. Tues. and Thurs. afternoons at 2 p.m.—Bethlem Royal Hospital, St. George's Fields, S.E. Course in Psychological Medicine. Lecture-demonstrations on Tues. and Sats. at 11 a.m. *Further particulars from the Fellowship of Medicine.*

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

Monday, Feb. 10th.—10 a.m., Dr. Dowling: Skin Department. 11 a.m., Mr. Tyrrell Gray: Surgical Wards. 2 p.m., Mr. Sinclair: Surgical Wards.

Tuesday.—10 a.m., Medical Registrar: Medical Wards. 2 p.m., Mr. Hamblen Thomas: Throat, Nose, and Ear Dept. 2.30 p.m., Sir Henry Simson: Gynæcological Operations.

Wednesday.—10 a.m., Dr. Burnford: Medical Wards. 2.30 p.m., Mr. Donald Armour: Surgical Wards. Dr. Scott Pinchin: Medical Out-patients.

Thursday.—11.30 a.m., Mr. Simmonds: Demonstration of Fractures. 2 p.m., Mr. Bishop Harman: Eye Department. 2 p.m., Mr. MacDonald: Genito-Urinary Department.

Friday.—10 a.m., Dr. Pritchard: Medical Wards. 2 p.m., Mr. Vlasto: Throat, Nose, and Ear Department, 2 p.m., Mr. Sinclair: Operations.

Saturday.—9 a.m., Mr. Vlasto: Throat, Nose, and Ear Operations. 9.30 a.m., Dr. Burnford: Bacterial Therapy Department. 10 a.m., Dr. Owen: Medical Children's Department.

Daily, 10 a.m. to 5 p.m., Medical, Surgical and Special *Out-patients. Operations.* Ward *Visits. Anæsthetic* Courses.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, Feb. 10th.—2.30 to 5 p.m.: Medical, Surgical, and Gynæcological Clinics. Operations.

Tuesday.—2.30 to 5 p.m.: Medical, Surgical, Ear, Nose, and Throat Clinics. Operations.

Wednesday.—2.30 to 5 p.m.: Medical, Skin, and Eye Clinics. Operations.

Thursday.—11.30 a.m.: Dental Clinics. 2.30 to 5 p.m.: Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

Friday.—10.30 a.m.: Throat, Nose and Ear Clinics. 2.30 to 5 p.m.: Surgical, Medical, and Children's Diseases Clinics. Operations.

CHADWICK PUBLIC LECTURE.

Thursday, Feb. 13th.—5.15 p.m. (in the Lecture Hall of the Medical Society of London, 11, Chandos-street, Cavendish-square, W.), Prof. B. Blacklock: Health in West Africa.

UNIVERSITY COLLEGE, Gower-street, W.C.

Monday, Feb. 10th.—5 p.m., Prof. A. V. Hill: Oxygen and the Recovery Process in Muscle and Nerve.

ROYAL NORTHERN HOSPITAL, Holloway.

Tuesday, Feb. 11th.—3.15 p.m., Dr. C. C. Beatty: *Demonstration of Cases.*

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

Monday, Feb. 10th.—1.30 p.m., Hearing Tests.

Wednesday.—1.30 p.m., The Sinuses: Examination and Diagnosis.

Friday.—4 p.m., Mr. J. D. McLaggan: Some *Complications* of Nasal Sepsis.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.

Wednesday, *Feb. 12th.*—4 p.m., Dr. J. Browning Alexander: The Investigation of Dyspeptic Conditions.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark Hill, S.E.

THURSDAY, Feb. 13th.—9 P.M., Dr. R. D. Lawrence: The Clinical Value of Chemical Investigations.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Feb. 11th.—5 P.M., Dr. E. Graham Little: Ulcus Molle.

THURSDAY.—5 P.M., Dr. J. E. M. Wigley: Lupus Erythematosus.

ST. MARY'S HOSPITALS, Manchester.

FRIDAY, Feb. 14th.—4.30 P.M. (at the Whitworth-street West Branch), Post-graduate Lecture, Dr. J. F. Ward: Vomiting in Infancy and Early Childhood.

SHEFFIELD POST-GRADUATE CLINICS.

TUESDAY, Feb. 11th.—3.30 P.M. (at the Jessop Hospital), Mr. King: Practical Antenatal Care and Its Limitations.

FRIDAY.—3.30 P.M. (at the Royal Infirmary), Mr. W. J. Lytle: Stone in the Urinary Tract.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

WEDNESDAY, Feb. 12th.—4.15 P.M. (at the Ear, Nose, and Throat Hospital), Cases by the Staff.

Appointments.

EDEN, G., M.D., B.Ch. Camb., has been appointed Hon. Physician to the Queen's Hospital, Birmingham.

LAWRIE, J. H. D., M.D. Edin., D.P.H., Medical Officer of Health for Macclesfield.

LILICO, G., M.B., Ch.B. Edin., D.P.H. Medical Officer of Health for Derby.

Vacancies.

For further information refer to the advertisement columns.

Abergele Sanatorium, North Wales.—Temporary Med. Supt. 15 gns. a week.

Barrow-in-Furness, North Lonsdale Hospital.—H.S. £150.

Bedford County Hospital.—H.S. At rate of £175.

Birmingham City and University, Joint Board of Research for Mental Disease.—Histological Asst. £4 weekly.

Birmingham General Hospital.—Res. Surg. Reg. £120–£140.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £150.

Bristol Eye Hospital.—H.S. £150.

British Red Cross Society, Clinic for Rheumatism, Regent's Park.—Clin. Pathologist (part-time). £250.

Burnley, Victoria Hospital.—H.P. At rate of £125.

Buxton, Devonshire Hospital.—Asst. H.P. At rate of £150.

Carlisle, Cumberland Infirmary.—H.P. Also H.S. to Special Depts. Each at rate of £155.

Carlisle, Cumberland and Westmorland Mental Hospital.—Deputy Med. Supt. £500.

Chelsea Health Soc. and School for Mothers.—M.O.

Chester Royal Infirmary.—H.S. £150.

Coventry and Warwickshire Hospital.—Hon. Asst. Dental Surg.

Croydon County Borough.—Asst. M.O., &c. £600.

Derby, Bretby Hall Orthopædic Hospital.—Asst. M.O. At rate of £150.

Derby, Derbyshire Education Committee.—Asst. School M.O. £600.

Derby, Derbyshire Royal Infirmary.—Ophth. H.S. H.S. Also Asst. H.S. Each £150.

Doncaster, Royal Infirmary.—Third H.S. At rate of £150.

Durham C.C.—Deputy County M.O.H. £1000.

Ealing, Borough of.—Asst. M.O.H. £600.

East Ham Memorial Hospital, Shrewsbury-road, E.—Hon. Asst. Ophth. S.

Gloucester County and City Mental Hospitals.—Med. Supt. £1100.

Golden Square Throat, Nose and Ear Hospital, W.—H.S. £100.

Great Yarmouth General Hospital.—Sen. H.S. £150.

Hackney Union Hospital, High-street, Homerton, E.—Dental S. £100.

Hornsey Borough.—Asst. M.O.H. and Asst. School M.O. £600.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Infants Hospital, Vincent-square, Westminster, S.W.—Clin. Asst. for Out-Patient Dept.

Ipswich, East Suffolk and Ipswich Hospital.—Cas. O. £150.

King's Lynn, West Norfolk and King's Lynn Hospital.—Hon. Physician.

Leeds, Tuberculosis Sanatorium, Killingbeck.—Asst. Res. M.O. £250.

Liverpool, Royal Liverpool Children's Hospital, Myrtle-street.—Res. Cas. O. £250.

Liverpool, Royal Children's Hospital.—Two Res. H.P.'s and two Res. H.S.'s. Each at rate of £60. Also Res. M.O. at Heswall Branch. At rate of £120.

London Jewish Hospital, Stepney Green, E.—Cas. O. At rate of £150.

Macclesfield General Infirmary.—Second H.S. At rate of £150.

Maidstone, Kent County Ophthalmic and Aural Hospital.—H.S. to Ear, Nose and Throat Dept. At rate of £200.

Maidstone, West Kent General Hospital.—H.S. At rate of £220.

Manchester, Ancoats Hospital.—Orthopædic H.S. Also H.P. Each at rate of £100.

Manchester Royal Infirmary.—Three Clin. Assts. Each £35 for six months.

Manchester, Victoria Memorial Jewish Hospital, Cheetham.—Anæsthetist. One gn. per session.

Manchester and Salford Hospital for Skin Diseases.—H.S. £100.

Margate, Royal Sea Bathing Hospital for Surgical Tuberculosis.—Radiologist. 100 guineas.

Miller General Hospital, Greenwich, S.E.—Res. M.O., Cas. O. and H.P. At rate of £250, £150, and £125 respectively.

Newcastle-on-Tyne, Wooley Sanatorium, near Hexham.—Asst. M.O. £350.

Norwich, Norfolk and Norwich Hospital.—H.S. £120.

Nottingham Hospital for Women.—H.S. At rate of £150.

Oswestry, Shropshire Orthopædic Hospital, and Agnes Hunt Hospital.—H.S. At rate of £200.

Plymouth, South Devon and East Cornwall Hospital.—Hon. Asst. S. to Obstet., &c. Dept.

Royal Northern Hospital, Holloway.—H.S. Also Res. Out-patient Cas. O. and Anæsthetist. Each at rate of £70.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.P. At rate of £100.

St. Bartholomew's Hospital, E.C.—Dental H.S. £80. Also three Asst. Dental S's.

St. John's Hospital, St. John's Hill, Wandsworth, S.W.—Second Asst. Res. M.O. £100.

St. Mark's Hospital for Cancer, Fistula, &c., City-road, E.C.—H.S. At rate of £75.

Salford Royal Hospital.—H.S. to Orthopædic Dept. At rate of £125.

Sheffield Royal Hospital.—Ophth. H.S. Also Res. Anæsthetist. Each at rate of £80.

Sheffield Royal Infirmary.—Asst. Cas. O. At rate of £80.

Southport General Infirmary.—Sen. H.S. £200.

Stirling District Mental Hospital, Larbert.—Jun. Asst. M.O. £300.

Taunton and Somerset Hospital.—Hon. Visiting S. or Two Asst. Hon. Visiting S.'s

Truro, Royal Cornwall Infirmary.—H.S. £170.

Walsall County Borough.—Asst. M.O. £600.

West London Hospital, Hammersmith-road, W.—H.P., Two H.S.'s and Res. Anæsthetist. Each at rate of £100.

Westminster Hospital, Broad Sanctuary, S.W.—Orthopædic Surgeon.

Willesden U.D.C.—Asst. M.O. £600.

Windsor, King Edward VII. Hospital.—H.S. At rate of £ 00.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Dunoon (Argyle), and Sandbach (Ches.).

Applications from Ophthalmic Specialists are invited for the post of Medical Referee under the Workmen's Compensation Act to deal with cases arising in the districts of the following County Courts:—Dewsbury, Leeds, Otley, and Wakefield (Circuit No. 14), Pontefract, Tadcaster, and York (Circuit No. 15). Applications should reach the Private Secretary, Home Office, Whitehall, London, S.W., not later than March 3rd.

Births, Marriages, and Deaths.

BIRTHS.

MCCAY.—On Jan. 27th, at Headington, Oxford, the wife of Dr. C. A. R. McCay, of a daughter.

VINER.—On Jan. 29th, at Chorley Wood, Herts, to Mona (née de la Mare), the wife of Geoffrey Viner, M.D., F.R.C.S., of 4, Harley-street, W.1—a daughter.

MARRIAGES.

ALLOTT—KYDD.—On Jan. 29th, at St. Paul's Presbyterian Church, Birkenhead, Eric Newmarch Allott, B.M., M.R.C.P., to Edith Mary, younger daughter of Mrs. Kydd and the late William Kydd, of Birkenhead.

BATES—PYKE.—On Feb. 1st, at St. Mary Abbot's, Kensington, Ralph Bates, F.R.C.S. Eng., to Evelyn Pyke, M.R.C.S., L.R.C.P., younger daughter of the late Lionel Pyke, Q.C., and Mrs. Pyke.

PUGH—CULLWICK.—On Jan. 29th, at St. Peter's Church, Wolverhampton, Mervyn Phippen Pugh, D.S.O., M.C., to Vera Cullwick, M.B., Ch.B., youngest daughter of Mr. and Mrs. H. E. Cullwick, of Wolverhampton.

ROFF—DYSON.—On Jan. 28th, at St. James', Birch, by the Right Rev. the Lord Bishop of Middleton, Chas. D. Roff, son of Mr. and Mrs. C. D. A. Roff, of London, to Margaret Dyson, daughter of Dr. and Mrs. W. Dyson, of Rusholme. At home, Feb. 27th and 28th, Beechfield, Wilmslow.

DEATHS.

BURY.—On Feb. 3rd, 1930, at Hollinwood, Darwen, G. W. Bury, M.D. Vict., F.R.C.S. Edin., aged 44.

CLAPP.—On Jan. 27th, at his residence, Downside, Whitchurch, Tavistock, Devon, Robert Clapp, Physician and Surgeon, M.R.C.S. Eng., L.R.C.P. Lond.

DAVIS.—On Feb. 3rd, at Bournemouth, Charles Daniel Davis, M.R.C.S., L.D.S. Eng., of Merstham, Surrey, and late of Streatham Hill.

DRABBLE.—On Jan. 31st, at The Grange, Walton-on-Thames, George White Drabble, M.A., M.B., B.C., in his 66th year.

ELLIS.—On Jan. 29th, at a nursing home in London, of peritonitis, William McDonogh Ellis, M.D., M.R.C.S., L.R.C.P., of "Greenbanks," Woldingham, Surrey, and late of Bath, Somerset.

KEKWICK.—On Jan. 27th, at "Ellerslea," Dalston, Cumberland, John Kekwick, M.R.C.S., L.R.C.P., L.D.S.

MACARTNEY.—On Jan. 27th, at Brighton, of heart failure, James Macartney, M.D., Lieut.-Colonel, late R.A.M.C.

SCOTT.—On Jan. 28th, at Saskatoon, James Matthews Duncan Scott, M.D. Edin., D.P.H. Camb., Professor of Physiology in the University of Saskatchewan, Saskatoon.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE ANTI-NOISE CAMPAIGN IN NEW YORK.

EVERY civilised community is finding itself faced with the problem of noise and the devastating effect of continual and excessive auditory stimuli on the nerves of the people. New York has tried to reduce the problem to mathematical terms by inventing a unit of sound—the "bel." Broadcasting a description of the work on Dec. 31st, Dr. Harvey Fletcher produced the sound of a motor horn ten feet away as an example of "nine bels" of sound. The noise in various parts of New York is being measured by producing a clear warbling note that can just be heard above the traffic roar and then measuring the intensity of the note in a "noise meter." This is a sensitive microphone which converts the sound waves into electric currents, which in turn are amplified and passed into an electric meter. The quality, as well as the quantity, of city noises is being tested by means of noise filters. The investigators are finding out the part played by specific sources—e.g., trucks, trolleys, building operations—in producing the aggregate noise, and also the pitch, range, and loudness of specific noises which are the cause of complaint. When this information has been collected it will be possible to make constructive proposals for noise abatement. Other workers are concerning themselves with the production of sound-proof buildings and of a combined window-ventilator and sound-muffler that will admit air without admitting noise. Mr. R. V. Parsons, an acoustical engineer, in a broadcast talk on Dec. 27th, maintained that sound-proof construction is possible and practicable for offices, homes, and public buildings to-day. While it is the task of architects to introduce improvements in design and construction, much can be done by furnishing the rooms with heavy-pile rugs and hangings and over-stuffed divans and chairs. Books, he observed, are very sound-absorbent. The American economist is convinced that quiet is worth paying for; last year $3,000,000 were spent in quieting American offices. Dr. Donald Laird has found that noise appreciably diminishes the concentration, memory, and speed of employees. Our noise problem may not be as serious as that of New York, but it is certainly bad enough, and it is to be hoped that those who suffer from the effects of modern noise will join with those who are concerned about its effect on the public health and create that public demand which alone will produce the supply of noise-proof devices for our homes and work-rooms.

HEREDITY AND ENVIRONMENT.

IN an address on the relative importance of heredity and environment in the development of the individual, delivered in London under the auspices of the British Social Hygiene Council on Jan. 30th, Mr. C. C. Hentschel remarked that heredity was taken very much for granted. It was expected that like should beget like, and it was not until we considered what a queer world it would be if there were no heredity—with the possibility of a sheep, for instance, giving birth to calves or lizards instead of lambs—that its real meaning became apparent. From the strict biological point of view, the changing of the environment did not seem to be likely to produce any immediate effect upon heritable traits. The question of the inheritance of acquired characters was still one of the vexed controversies of biology, which must be left to the future for solution; and there was little evidence at present to show that the environment could—except perhaps over a long series of generations—produce any marked effect on racial characters. What the environment was able to do was to produce from the organism those characteristics which it had received as its inheritance, and to give them the fullest opportunity for coming to fruition. It was a waste to sow good seed on a barren soil, just as it was a crime to use rich soil for worthless seed. Only if the rich soil was reserved for the good seed could we hope for some permanent racial benefit.

An abstract of Mr. Hentschel's previous lecture on Biology and the Training of Youth appeared on p. 256 of our last issue.

BREADMAKING.

THE aim of a book on breadmaking by Mr. E. B. Bennion[1] is to show that a *proper application of the fundamental* principles of physics, chemistry, and biochemistry is essential to the practical art of breadmaking. Many chapters of the book are devoted to such problems arising in the bakehouse as the choice and testing of raw materials; the changes involved in fermentation, baking and cooling, and the effect of varying physical and chemical environments on these changes; the advantages and disadvantages of the straight-dough and the sponge-and-dough processes; recipes; the judging qualities and faults in bread; and the diseases which may arise in flour, yeast, and bread. Other chapters deal with the comparative efficiency of different types of fuels, ovens, and machinery used in the bakehouse, and the final chapter is concerned with the dietetic value of bread compared with other foods.

WAITING-ROOM LITERATURE.

MUCH admirable volunteer work is being done in the Rhondda Valley in behalf of young boys and youths the victims of unemployment, and an appeal is being made to medical men to come to the assistance of this work in a useful direction. In many medical waiting-rooms there is a large and varied assortment, up to date or otherwise, of illustrated papers and magazines, and it is suggested that the doctors might be willing to send the old issues of this literature as newer ones appear to a collecting centre in the Rhondda for distribution to these lads. The Editor of THE LANCET will be happy to receive the names of those who are willing to coöperate, when an arrangement will be made by which stamped and addressed wrappers for a certain period ahead will be supplied to them. The particular boys for whose sake this suggestion is being made are received regularly in a hut-shelter for instruction and entertainment, and the eagerness has been noticed with which they seek all sorts of general and special instruction. The doings of smart society at home and abroad and at social or sporting functions would have no interest for this audience, but they are hungry for newspapers, magazines, or manuals in which the phenomena of the world and the serious sides of life, its careers and occupations, are recorded. All literature dealing with natural history or providing technical training, as far as the printed word can do this, will be devoured. The gratitude which those who can help in this way will earn can hardly be exaggerated.

"WHERE TO PARK YOUR CAR."

A COMPLETE handbook of parking-places in every part of the United Kingdom and the Irish Free State is issued under this title by the Roadway Time Tables Bookings and Publications, Ltd., Regency House, London, W.1, at 1s. The book has been brought up to date, and in its fourth edition, of nearly 300 pages, gives information about the charge and attendance, if any, the limit of time during which cars may be parked, and the places where automatic traffic signals are in use. The convenience to tourists of knowing in advance where to make for when visiting a strange town is considerable; once the car is safely stowed away a survey can be made of the most acceptable sources of interest or refreshment without fear of infringing local regulations. Travellers from London will be cheered to note in how many provincial towns no time limit is fixed for cars in parking-places. The parking-places within 15 miles of Charing Cross are not very conveniently arranged in the book. It is difficult to see on what basis the districts are classified; the list starts with Westminster and ends with Erith. An index shows the name of the roads in alphabetical order; for example, Adelaide-road, Southall, heads the column, but the other Southall parking-place is indexed under Lady Margaret-road, Southall, and if the reader starts with a wish to find the parking-places in Southall he must either search this index with some care or find Southall (between Kingston and Slough) in Section IV. of the book. The remedy would be to rearrange this section in alphabetical order.

GAS FIRES AND THEIR SETTINGS.

A LITTLE book[1] by the late Sir Lawrence Weaver deals with the artistic or æsthetic rather than with the practical use of gas heating. His efforts will, we hope, influence architects to work out methods of treatment for this efficient heating agency. Cumbersome and ugly chimney-pieces often spoil otherwise pleasant rooms, and are unnecessary when these are heated by gas. Anyone building a new house or rearranging fireplaces will welcome this book; special attention should be paid to Figs. 26, 27, and 28, showing gas fireplaces installed by Sir Giles Scott in his own house. On the more practical side of gas heating we would commend to the ingenuity of gas engineers for solution the problem of the man recently portrayed in *Punch* who desired a lamplighter's long tube in order to light his bedroom gas fire without getting out of bed. This would be a great convenience to invalids.

Hunterian Lecture

ON

MASSIVE COLLAPSE OF THE LUNG.

Delivered before the Royal College of Surgeons on Feb. 7th, 1930,

BY SIR JOHN ROSE BRADFORD, K.C.M.G.,
M.D. LOND., F.R.S.,

PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON; CONSULTING PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL AND THE SEAMEN'S HOSPITAL.

MR. PRESIDENT, FELLOWS OF THE COLLEGE OF SURGEONS AND GENTLEMEN,—I find it somewhat difficult, Sir, first of all to express in an adequate manner my thanks to you and to the College for giving me the opportunity of speaking to you here this afternoon. I think I am correct in saying that this is the first time on which the occupant of the office I have the honour to hold at the moment has had the opportunity of speaking in this theatre. I am quite sure the College of Physicians has the same views as myself with regard to this, and looks upon it as a most happy innovation; and I only hope that my own College may be able in the future to return the compliment and to ask one of the Fellows of this College to address them. Although I greatly appreciate the compliment that has been paid to my College, this increases the difficulty I am labouring under in addressing you to-day, because, obviously, the occasion is one which ought to be made full use of, and I ought to have something of interest, if possible, to bring before you. I am afraid that by the time one reaches the period of life that I have arrived at, it is difficult to contribute anything really to the advance of knowledge; one has to look to the younger men to do that. I am well aware, if I may say so, of the difference of the circumstances under which I am speaking in this theatre now and the occasion on which I had the pleasure of speaking in it very nearly forty years ago. Perhaps I ought not to have alluded to this, but I really could not help alluding to it; it is a fact that the first lecture I gave to a medical audience was given in this College, and I suppose this is the last lecture I shall give to a medical audience; and I am grateful to you, Sir, and to the College, for that notwithstanding that I feel I have nothing very suitable to bring before you. I beg to thank you very sincerely.

In seeking for a subject on which a physician could address a gathering of surgeons, I thought I would try to find something which would appeal to both branches of our profession; and that was my main reason for selecting the subject "Massive Collapse of the Lung." I am afraid I have nothing very new to say on the subject, but it is one that has always struck me as singularly interesting, because of the mystery attached to it. It has always seemed to me a phenomenon which, on the surface, would appear to have a very simple and purely mechanical explanation and yet probably that is not so, there is probably a more complex mechanism at work. Further, it is a subject, at any rate, on which knowledge is not very widely disseminated. It is a condition that is very often overlooked, and it is a condition which is always obscure and difficult to interpret.

It is not quite fifty years ago since it was first described, and, as you probably all know, the two names which stand out conspicuously in the history of the subject are those of Pearson Irvine in the first place, and Pasteur in the second place.

INCIDENCE.—FREQUENCY.

First with reference to its incidence. Massive collapse of the lung is seen, of course, in civil practice, and was seen in a large number of instances in military medicine and surgery. A great deal of our knowledge of the subject has been derived from the observations which were made, under exceptionally favourable conditions, in the late war; the conditions under which it occurred there were often somewhat more simple than those in which it is seen in civil practice. In civil practice, speaking broadly, massive collapse is seen as a complication of some underlying, and usually more or less grave, condition. In military practice, on the other hand, although, no doubt, it is often seen similarly as a complication in grave cases of various injuries, it is also seen in conditions which may be described as comparatively trivial, some of them, indeed, quite trivial. Hence the problem of its nature and the various facts in connexion with it are more easily elucidated than they are in civil practice.

As regards its frequency, one has great difficulty in making any statement that is of value, owing to the large number of instances in which it is overlooked. Those who are interested in the presence of massive collapse and are familiar with its more or less characteristic physical signs will find it in a very considerable proportion of cases; on the other hand, some of the most extreme cases of the condition may be entirely overlooked by those who are not familiar with its clinical picture. Therefore it is very difficult to make any statement with reference to its frequency. The reasons for that, apart from the one I have mentioned, are, that it frequently occurs as a complication, and consequently its presence is overlooked owing to the attention being concentrated on the underlying condition. Furthermore, it is overlooked for another reason—namely, that it is liable itself to be followed by inflammatory complications, and then, unless it has been previously recognised, it is, almost necessarily, not recognised. There are many reasons, therefore, as far as my experience goes, for thinking that no very accurate statement can be made with reference to its frequency.

ÆTIOLOGY.

Now as to its ætiology. Its ætiology is certainly very complex, and that suggests that there are probably many varieties, or at any rate several varieties, of massive collapse. It is difficult to believe that there can be simply one cause for it when, as you will see in a few minutes, the factors in its production are so various. Originally, cases which were described by Pearson Irvine were cases in which the condition was dependent on palsy of some kind. Originally it was described, as probably you know, in cases of diphtheritic paralysis. Another large group of cases, particularly those which Pasteur treated of, were those in which many factors came into play, as—for example, anæsthetics, operations, posture, &c. They were cases seen in operations of varying degrees of severity, especially operations in the abdominal region—hernias, appendicitis, and various other conditions. Some have thought that the condition was especially associated with operative procedures in the upper portion of the abdomen. But, of course, it is clear that where you have such conditions as palsy, such conditions as the use of anæsthetics and operative interference, all kinds of questions arise and it is difficult to trace the chain of events.

To consider further the question of ætiology, in many of the cases you not only had more or less severe operative procedures, but there were also severe underlying diseases present, possibly even peritonitis. In many others there were very severe injuries: fractures of pelvis or thigh, conditions which necessitated immobilisation of the patient. It may be said, broadly, that in civil practice, therefore, the conditions leading to the subsequent development of massive collapse were singularly complex.

Now, in military practice, as a result of gunshot wounds, especially of the chest, no doubt [illegible] cases the conditions here also were

Any physician or surgeon who had experience of chest wounds in the late war would recognise at once the extraordinary variety of the lesions produced, and the complexity of the lesions and the complexity of what the physician talks of as physical signs. But there were other cases in military practice of chest wounds where the conditions were by no means very complex.

The chest wounds are divided conveniently into the (*a*) penetrating, and (*b*) the non-penetrating, and in any discussion as to the nature of massive collapse one is inclined to lay more stress on the simpler non-penetrating lesions of the chest than on the penetrating lesions; but even in a non-penetrating wound of the chest conditions may be very complex. For example, every one familiar with wounds of the chest knew that in non-penetrating wounds such a phenomenon as hæmoptysis was of common occurrence, and if you have such a phenomenon as hæmoptysis the problem of the ætiology of massive collapse is immediately rendered exceedingly difficult. Hæmoptysis might conceivably be a factor even in such a remarkable variety of massive collapse as that described as "contralateral," because with a non-penetrating wound of the chest producing hæmoptysis it is obvious that blood might be drawn down into the opposite lung. So in any discussion as regards the mode of production of massive collapse I would suggest that in military practice not only must one eliminate the consideration of cases of penetrating wounds of the chest—because there the conditions are too complex—but one must also eliminate cases of non-penetrating wounds of the chest where such a phenomenon as hæmoptysis has been present. If you eliminate those groups the number of cases which is left is relatively small, but they are singularly instructive, as we shall see in a moment.

There are a considerable number of cases of chest wounds limited to the parietes of the chest where there is no reason to think that any appreciable injury has been inflicted on the lung on that side, and it is more especially with reference to that type of case that I propose to ask your attention.

I suggest, then, that first of all in massive collapse in discussing the ætiology of it one has to consider several varieties; that in some of these one may have to deal with questions of definite palsy of the respiratory muscles, in others one may have to deal with questions of bronchial obstruction. But, in addition, there is a certain definite group of cases in which these phenomena, humanly speaking, can be eliminated, and where one has to invoke some other mechanism. The consideration of the facts in that last group of cases necessarily raises the question or the suggestion as to whether a similar line of argument may not be applied to the first two groups, and suggests that if the third variety cannot possibly arise either as a result of obvious palsy or as a result of obstruction of the bronchial passages, it may well be that in the cases where the condition arises apparently as a result of these, this is not really the case.

PHYSICAL SIGNS.

Now to pass on to say a few words with reference to the physical signs of massive collapse. If there is one lesson which was impressed on a physician more firmly than any other in the course of his medical practice in the late war, where he had unrivalled opportunities of studying physical signs, it was the necessity of revising some of our cherished convictions as regards the interpretation of physical signs, and I do not think there is any lung condition which plays a greater part in that than a study of the physical signs of massive collapse, because they are very remarkable.

They are, apparently, very elementary and very simple, but the more one studies them the more one doubts their being as simple as they seem to be. The first thing which strikes one as regards the physical signs of cases of massive collapse is the immobility of the chest on the affected side. That seems a trite statement. We have been taught that the chest is immovable in pleural effusions, and so on; but the immobility of the chest in a case of pleural effusion is quite a different immobility to that of the chest which is seen in massive collapse; one is a relative immobility, the other is an absolute immobility. I know of no condition, as regards physical signs in the chest, in which absolute immobility is so marked and characteristic as it is in massive collapse. You may think, gentlemen, that one lays too much stress on these comparatively simple things, but that is not my view.

It is convenient to describe the physical signs of massive collapse as running through three stages: in the early stage, when you have this very marked immobility, you have, also, weakness—or even absolute extinction—of the breath sounds. Now, weakness of breath sounds is, apparently, a very trivial observation from the physical sign point of view, one that often is very little stressed. It is described as one due to many different causes. Absence or diminution of breath sounds in massive collapse is a phenomenon much more marked than in the more usual conditions which we associate with that physical sign. In the early stages of massive collapse these are leading physical signs. But the most important physical sign, the one that probably, in the vast majority of cases, leads to the immediate recognition of the condition by those experienced in it, is the extraordinary displacement of organs which takes place, particularly of the heart and of the abdominal viscera, owing to the displacement upwards of the diaphragm. There have been remarkable mistakes made as a result of overlooking this condition. In my experience in France I saw many cases in which pneumothorax was diagnosed, and yet the real condition was that the left side of the diaphragm had been displaced so high that the tympanitic resonance of the stomach was reaching the third or fourth rib, and so was mistaken for pneumothorax, sometimes with unpleasant results. To give you an idea of the extraordinary extent of the displacement: the heart way be displaced to a degree to suggest congenital transposition of viscera. I have myself made the mistake in a case of massive collapse of the lung of thinking that there was no massive collapse present, and that it was a case of congenital transposition of the viscera. That will give you an idea of the extreme displacement which may take place, without necessarily the development of any symptoms at all.

So one would lay stress on the great immobility of the chest wall on the affected side, on the extraordinary degree of displacement of the contents of the thorax, such as the heart, and the extreme displacement of the abdominal viscera owing to the high position of the diaphragm.

In the second stage of the condition, weakness of breath sounds becomes replaced by what is described as tubular breathing; and it is the most perfect tubular breathing that one is acquainted with. It may reach a degree of development even greater than that which we are familiar with in lobar pneumonia; it may reach a degree which justifies, almost, the term "cavernous." And inasmuch as the area of massive collapse may often be a very large one, I need not say that physical signs of that description over a very large area, without the patient, perhaps, presenting very marked symptoms, leads to extraordinary confusion sometimes in the mind of the observer, because he has been so convinced in his training that breathing of that character must mean pneumonic consolidation, that he fails to recognise the tubular breathing of massive collapse that may be even more marked than in pneumonic consolidation.

In the later stage of the condition you have the development of a number of moist sounds, abundant râles and crepitations, or, to put them in their proper order, crepitations and râles, with the result, again, of producing a clinical picture extraordinarily similar to that of pneumonia.

The symptoms of the condition are not very characteristic, and they are extremely variable. There may be a degree of massive collapse not, perhaps, so great as that seen in this specimen before you, but not far short of that, and yet without the presence of any obvious symptoms at all, at any rate when the patient is in bed. But, as I have recorded elsewhere, I have known the case of a man who was hit in the lower part of the chest, at the back, by a bullet, which produced such a superficial wound that it dropped on the floor when he took off his clothes, and he had walked four miles after he had been hit. He was admitted into hospital on the evening of the day he was hit, and he had no appreciable discomfort of any kind, yet he had collapse of the whole of one lung, on the side opposite to that wounded, symptoms may thus be entirely absent. In other cases dyspnœa, of varying degrees of urgency, may be present, and in the later stages of the condition, more especially when those fine râles and crepitations which I alluded to before are present, the patient may have some cough and some expectoration. The essential clinical fact is that you may have a very large area of one lung thrown out of gear and made useless from the respiratory point of view, without the development of any serious symptoms to attract attention.

SITUATION.

As regards the situation of a massive collapse it is most commonly present in the basal portions of the lung. Perhaps the seat of election is the upper part of the middle third of the lower lobe, but it may involve the whole of one lung. I have not been absolutely satisfied, from my own observation, of massive collapse involving the apex only. Of course, you have the apex involved when the whole lung is implicated, but I do not dogmatise about it, because it is a difficult observation to make. In some cases the condition is bilateral, and here again it is often difficult to recognise, because if there is weak breathing at both bases you have lost your standard, and it is very difficult to be absolutely certain of the diagnosis short of X ray examination, and that has not always been possible.

COURSE.

As to the course of the condition, one of the striking features of it is the rapidity with which the physical signs change. I mentioned a moment ago—and I revert to it because I think it is a very instructive case—where an error of diagnosis was made through looking upon the case as one of congenital displacement of the heart. It was the case of a man with a trivial wound of the clavicle on one side, and he had massive collapse of such a degree as to cause the heart to be beating just internal to the right nipple, so there was extreme collapse of the right lung. I was taken to see that case—as it was known I was interested in massive collapse and it was thought it might be an instance. The complete absence of any symptoms led me to think there was no massive collapse, and that it was an instance of transposition. In that case the heart went back to the other side in 30 hours. That gives you an indication of the rapidity with which the physical signs may change, even in the most extensive massive collapse.

Inflammatory complications may occur. The case may begin as one of massive collapse, and then it may become complicated by pleurisy, and even by the pouring out of fluid. Or it may be complicated by broncho-pneumonia, by confluent lobular pneumonia; and then, unless you have seen the case from the beginning a diagnosis would be impossible, because then the case resembles ordinary pleural effusion or broncho-pneumonia.

DIAGNOSIS.

With reference to diagnosis, I have perhaps said enough already to point out that the diagnosis is often difficult, and it may be especially so in some cases of what is spoken of as contralateral massive collapse, understanding by that term cases in which massive collapse occurs on one side of the chest after an injury to the other side, and sometimes a comparatively trivial injury. The diagnosis is generally arrived at by considering the physical signs which I have mentioned—namely, the extreme immobility, the extreme displacement, together with the absence of marked symptoms. But extraordinary errors are liable to be made, some of which I have already mentioned, as, for example, imagining that the mischief is on the opposite side of the chest to that on which it really is, and the diagnosis of pneumothorax as a result of mistaking the gastric resonance for air in the pleural cavity.

THE NATURE OF MASSIVE COLLAPSE.

To pass, now, to the more interesting question as to the nature and mode of production of massive collapse. In discussing that, we have to consider the relation of the chest wall to the underlying lung. Now, Mr. President and gentlemen, the relation of the chest wall to the underlying lung is, I think, more complex than many of us in our everyday work think; we are rather overpressed with the idea of the relation being an entirely mechanical one. Of course, there is a mechanical relationship between the volume of the lung and the volume of the chest. Any of you who have examined a young child with reference to whether any pulmonary lesion is present knows that if a child with a soft chest is placed face downwards on the nurse's knee, that unless the nurse holds the child perfectly straight—that is to say, if the spinal column is a little curved, thus hampering the movements of the chest, this hampering, slight as it is, will, in the child, produce a perfectly definite area of dullness, which can be marked out by percussion, and produces weak breath sounds. And when the chest is straightened again and the child takes a deep breath, crepitations, &c., may be heard. Many a young student makes an erroneous diagnosis of the presence of pneumonia because he has not taken precautions to see that the two sides of the chest are symmetrically disposed when it is examined in this way. That is a very striking instance of the extreme case with which limitation of the movements of the chest will immediately produce effects in the underlying lung.

So I do not think anything more need be said with reference to the anatomy and close mechanical relations existing between the volume of the lung and the size of the chest. But, above that, there is a vital, a living relationship between the two. There are experiments—of many years ago now and often forgotten—of Hering and Breuer, subsequently extended by Head in this country, showing the most extraordinarily delicate relationship between the volume of the lung and the tonus of the chest wall. Those who have seen these experiments will agree that there is an extraordinarily complex relationship between the volume of the lung and the tonus of the musculature of the chest. The slightest diminution of the volume of the lung by sucking a small quantity of air out of the trachea produces, reflexly and *immediately*, *an increase in the tonic contraction* of the diaphragm and of the inspiratory muscles, with the result of neutralising the sucking of the air out, and causing the intake of a larger volume. It is one of the most delicate reflexes known to the physiologist, and it is a most beautiful example of a pressure stimulus. A diminution, by a few millimetres, of the pressure of air in the bronchial tree immediately produces a reflex, leading to an increased tonic contraction of the diaphragm and other inspiratory muscles. Conversely, the raising of the pressure produced by a very slight puff, barely audible, will produce an immediate expiratory tonus. So that, apart from the mechanical relationship existing between the volume of the lung and the volume of the chest, there is a very delicate complicated reflex nervous mechanism between the two, and this must be borne in mind.

MECHANISM OF PRODUCTION.

Now a few words with reference to the mechanism of the production of massive collapse. It would seem that if it is true—as it unquestionably is—that a very slight lesion incapable of producing severe symptoms on one side of the chest may, in the course of a few hours only, lead to extreme collapse of the opposite lung, it is difficult to see that this can be due to any other cause than a reflex mechanism of some kind. You cannot invoke bronchial obstruction to explain such a condition as that, and it is difficult to see how you can invoke any palsy. There must be some reflex mechanism. If there be a reflex mechanism of that kind, is it that the lung first of all becomes collapsed and then the chest wall, following it, becomes immobile? Or is it that the chest wall becomes immobile and, as a result of that, the lung collapses? We know that if you impede the respiratory movements, or if you obstruct the bronchial tree, the rate of absorption of the air of the lung is extremely rapid. So there is no particular difficulty in understanding that collapse of the lung should be brought about if, by some mechanism, immobility of the chest wall is brought about. On the other hand, it is difficult to believe that there can be, as the result of an injury of the chest wall, any activation of a reflex mechanism which acts directly on the lung. I know it has been suggested that possibly the involuntary muscular tissue in the lung may lead to its contraction. It has also been suggested that there may be reflex effects on the vessels of the lung. It would take too long to discuss these points, but they are not very plausible hypotheses. On the other hand, though one cannot say what the nature of the reflex mechanism is, yet it is not incredible that there may be a reflex mechanism which may lead to immobility of the chest wall. At any rate it is very difficult to believe that the phenomena can be due to any primary obstruction of the bronchial tree, either by spasm, or by blood, or by secretions, or what not. Blood and secretions, &c., are rather excluded, *ab initio*, by limiting our consideration to the cases of contralateral massive collapse following trivial injuries of the chest wall. Further, I think the main reason one is sceptical as to any primary mechanism of bronchial obstruction is that surely all varieties of bronchial obstruction which we know produce symptoms, and it is very difficult for me to see that you could have such a degree of bronchial obstruction brought about as to lead to collapse of the whole of one lung and yet the patient have no symptoms of distress of any kind. Therefore I incline rather more to the view that there must be a reflex mechanism of some kind which acts primarily on the wall of the thoracic chamber, both on the diaphragm and on the intercostal muscles, and in that way brings about the immobility of the chest; and, as a result of this, the air in the lungs is absorbed and massive collapse ensues.

CONCLUSION.

Mr. President and Fellows of the College, those are the main considerations which I wished to put before you. I am quite aware of the fact that it is by no means a satisfactory or complete, or even a partial, explanation of the phenomena of massive collapse; at the same time, I think that the study of this condition, particularly when it occurs in association with simple injuries, is of great interest, and one in which we are dealing, perhaps, as I hinted earlier in my remarks, with a condition where there is really at work some mechanism more complicated than a mere mechanical relationship between the contents of the thorax and the parietes. Of course, a superficial comparison which must occur to anybody who thinks about the condition is, that it presents some resemblances to the rigidity of the abdominal wall which we are familiar with in abdominal diseases. Whether it is more than a superficial resemblance I do not know, but at any rate I suggest that those who have the opportunities of observing the occurrence of this condition—and surgeons are more likely to have these opportunities than physicians—will be able in the near future to throw more light on the nature of its causation.

An Address
ON
SOME MODERN ASPECTS OF
CHOLECYSTITIS AND CHOLELITHIASIS.

Delivered before the Manchester Surgical Society on Feb. 4th

BY A. J. WALTON, M.S. LOND., F.R.C.S. ENG.,
SURGEON TO THE LONDON HOSPITAL.

INCREASING knowledge of the pathology of the gall-bladder is making it evident that disease of this organ is one of the commonest causes of dyspepsia and ill-health. In my own series there have been 574 cases. Although the total number of peptic ulcers in the same time-period has been 1277, the number of gall-bladder lesions has been greater than the ulcers of any one group—namely, 401 duodenal, 389 lesser curve, and 188 pyloric ulcers. It must be realised also that the greater number of these cases of gall-bladder disease were grosser examples which were associated with gall-stones, for it is only within recent years that it has been widely appreciated that cholecystitis may be present and may cause a considerable impairment of the general health without having as yet led to the formation of calculi.

My own figures support the well-known views that the disease is much more commonly found in women, there being 451, or 78·5 per cent., females. Especially common is it in extremely fat women. Although these are two of the earliest known points in our knowledge of the disease, so that the formation of gall-stones has long been regarded as a just retribution for a life of greed, yet we are far from understanding why calculi should be so much more common in women, and in women of this type. Indeed, with the increase of our knowledge the understanding of these facts has become more difficult.

FORMATION OF CALCULI.

In the investigation of the cause of cholecystitis and calculi formation one fact is outstanding, and that is that the majority of calculi are largely formed of cholesterol. Although this substance is normally present in the bile, is apparently present in larger quantities in women, and is greatly increased both in the blood and bile during pregnancy and some diseases, it appears to be quite certain that it is only found in those stones which are formed in the gall-bladder. In some cases it may be pure, giving rise to a relatively small solitary calculus which is formed of amorphous cholesterol or is slightly tinted with bile-pigment; in other cases a certain percentage of calcium carbonate and pigment may be present. It would thus seem natural to believe that this cholesterol had been simply deposited from the bile owing to the concentrating effect of the gall-bladder action, especially if the cholesterol-content of the bile is above normal. There are, however, as will be shown presently, many reasons against the acceptance of this view.

The other main group of calculi are those formed of pure pigment calcium. They are much less common, only 45 of my series being of this type, and appear to be generally formed in the ducts. If calculi are found at birth or in very young children, or are primarily deposited in the intrahepatic ducts, they are always of pure pigment calcium and may be formed in the absence of any inflammatory change. They are also found in a very large proportion of cases of acholuric jaundice, when they may be deposited in the gall-bladder or in the bile-ducts, and if removed from the gall-bladder, or even if a cholecystectomy be performed, they will almost certainly recur in the ducts unless the spleen has been removed. It thus seems certain that this particular variety of calculus may be formed owing to a metabolic error. Like the other varieties of calculi, they may also, however, be deposited owing to inflammatory changes; thus true recurrent calculi in the common bile-duct occurring after cholecystectomy and due to the presence of cholangitis are formed of pigment calcium alone.

In my opinion the other varieties of calculi always owe their inception to the presence of chronic inflammatory changes, and the evidence that has often been adduced that there is here also a metabolic change does not appear to be sufficient. They occur much more commonly in middle age. In my own group 320 occurred between the ages of 40 and 60. In every case in which calculi other than those of the pure pigment type have been removed, there has always been evidence of a chronic inflammatory change in the gall-bladder. The suggestion that this change is secondary to the gall-stones and is not their cause would not appear to be correct, for it is relatively common to find inflammatory changes in the gall-bladder with no calculi, but calculi without inflammatory changes are never seen. The recent work of Illingworth and Wilkie, showing that the infection is in the substance of the gall-bladder wall and not in the mucous membrane, strongly supports the view that the inflammation is the primary change. The careful examination of any calculus will show that usually its whole structure and always its outer layers are deposited in an amorphous form and never occur as crystals. If crystals are present they are found only in the centre of the calculus and are probably due to a secondary change. If the constituents of the calculus had been simply deposited from a super-saturated solution, they would certainly have come down in a crystalline form. The amorphous deposits occur, however, always in association with an organic matrix, and are therefore almost certainly deposited by a process of adsorption. Thus it is that a biliary calculus cannot be made to dissolve in a solvent of cholesterol or bile-pigment.

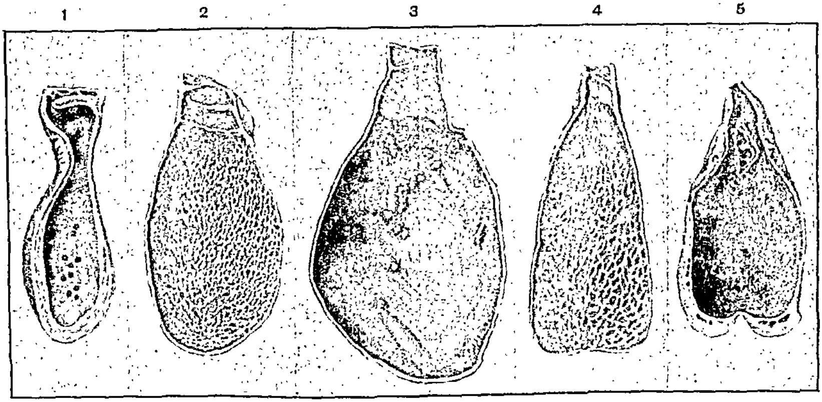

FIG. 1.—Typhoid cholecystitis showing gross changes in the bladder wall and only a few small calculi.
FIG. 2.—Strawberry gall-bladder as removed at operation. It contained one small stone.
FIG. 3.—Lipoid deposits forming papillary masses in the gall-bladder. There were no stones.
FIG. 4.—Strawberry gall-bladder found post mortem in a patient who died of eclampsia. There were no stones.
FIG. 5.—Intramural calculi. Several stones are seen in cystic spaces in the wall of the gall-bladder. There were none in the lumen.

In a large number of the cases the clinical history dates back to an infection. In the past this was commonly typhoid fever, but now that this disease is becoming a rarity it is not uncommon to find a past history of influenza, pneumonia, or some other infection from which the gall-bladder symptoms date. It is well known that in cases of typhoid fever acute cholecystitis may occur during the course of the active disease, and under such conditions gall-stones are not found. It is only of recent years that it is becoming appreciated that symptoms of mild cholecystitis may occur with many forms of general infection, that dyspeptic symptoms may be initiated at this time, and that it is only later that evidence of gall-bladder disease dominates the clinical picture. In some of these infections a very gross and marked change may be found in the gall-bladder wall, while gall-stones are very small or absent. An interesting example of such is the specific typhoid cholecystitis which is shown in Fig. 1. The patient had had typhoid fever two years before and had become a typhoid carrier, typhoid bacilli being present in the stools. The gall-bladder shows a very great thickening of its wall, but only a few small stones. After removal of the gall-bladder the patient ceased to be a carrier, the typhoid bacilli disappearing from the stools. It seems almost certain that in cases of this sort the cholecystitis is the primary change and that the gall-stone formation is a secondary effect.

It is in the formation of pure cholesterol calculi especially that claims have been put forward that the stones are primary and are not due to a past infection. The work of Aschoff and Bacmeinster is well known in this connexion, but here again it is difficult to accept their views, for such calculi always occur as a single stone in a dilated gall-bladder and are never formed in the ducts, and it is difficult to see why this should be the case if they originated as a simple deposition of cholesterol. My own experience with this variety is very definite. There have, in my series, been 23 examples, every one of which showed inflammatory changes in the gall-bladder, eight being associated with acute cholecystitis and 15 with chronic.

That curious condition known as the "strawberry gall-bladder" is perhaps not quite so definite. There is here a lipoid deposit which Boyd has shown to be an ester of cholesterol (Fig. 2). It is most commonly seen as streaks which are deposited in the apices of the swollen folds of mucosa. It may actually occur in the epithelial cells or in the delicate areolar tissue beneath. These streaks are usually distributed over the whole of the gall-bladder lining, but end abruptly at the commencement of the cystic duct. In some cases, however, it is aggregated in localised masses so as to form small yellowish-white papillomata (Fig. 3), which are most commonly situated in the fundus of the bladder. This method of deposition and limitation to the gall-bladder itself would suggest at first sight that the deposit was due to a metabolic change. The well-marked specimen illustrated in Fig. 4, which was obtained from a patient who died from eclampsia in pregnancy, would seem to support this view. Illingworth has shown, however, that the condition usually occurs in association with a mild cholecystitis, although at times it appears to be primary. In 17 of his 35 cases gall-stones were present. He also made the interesting observation that it could not be produced experimentally by increasing the blood cholesterol, but could be obtained by simultaneously increasing the cholesterol and infecting the gall-bladder wall. Baumgartner found that the condition was relatively common, it being present in 23 per cent. of all lesions of the gall-bladder, and stones being present in 50 per cent. of the cases. It seems probable, therefore, that even in this condition the primary change is inflammatory.

Interesting cases are occasionally seen in which stones appear to be present in the wall of the gall-bladder, but it is probable that these are not developed in the submucosa but in small hernial protrusions of the mucosa which have been shut off. The specimen seen in Fig. 5 shows several cystic-like spaces at the fundus which appear to be of this nature.

One of the strongest arguments that has been brought forward in support of the metabolic theory is the fact that some 75–80 per cent. of all cases of gall-stones occur in women who have had children, and, as it is known that the blood cholesterol is increased during pregnancy, it has been assumed that this change might account for the deposition of the stones. As in so many general observations of this sort, no attempt has been made to obtain controlled observations, and before we arrive at this conclusion we must know definitely what is the proportion of women between the ages of 40 and 60 who have had children. It is very probable indeed that in the general population at least 75 per cent. of women of this age are the mothers of children.

PATHS OF INFECTION.

Even if the above evidence be accepted that all calculi other than a few of the pure pigment calcium type are due to an infection of the gall-bladder, one can only hope in the future to prevent such changes if one has a complete understanding of the method by which such an infection reaches the bladder. The difficulties in obtaining such knowledge are increased by the fact that there are so many possible paths. These may be considered as follows: (1) up the common and cystic ducts; (2) along the portal vein, through the liver and into the bile, and so along the ducts to the gall-bladder; (3) by means of the systemic circulation; and (4) by direct or lymphatic spread from the liver, or some other organ such as the appendix.

It is natural to suppose that where there is an open path from the gall-bladder to the duodenum which normally contains organisms the easiest path of infection would be up this duct. This view was supported by the early observations that infections of the gall-bladder were most commonly due to *Bacillus typhosus* or *B. coli.* Hurst's observation that the achylia which is not infrequently found with gall-stones is dependent upon gastritis and may lead to an increase in the number of organisms in the duodenum is evidence in support of this view. It is, however, remarkable that increasing knowledge seems to show that what might be regarded as the natural paths of infection are, as a rule, so well protected that they are but rarely used. It is being realised, for instance, that infection of the kidney hardly ever takes place up the lumen of the ureter, nor do infections of the stomach usually arise from the ingestion of infected food. In the same way there is a considerable amount of evidence that ascending infections of the gall-bladder are rare. It is known, for instance, that the duodenum contains fewer organisms than any other portion of the intestinal tract, also a cholangitis even of a mild degree is a rare complication of gall-stones, and is practically only found as a sequence to, and not as a precursor of, gross disease of the gall-bladder. It has been frequently found also that in cases of chronic cholecystitis organisms could not be obtained from the bile, although in many cases they were found in the centre of gall-stones. Illingworth and Wilkie's observation that organisms are more common in the wall of the gall-bladder is also a strong argument against the possibility of this path of infection. The interesting fact has also long been known that whereas with typhoid fever it is very frequent to find *B. typhosus* in the bile, a cholecystitis is relatively rare, thus seeming to show that an infected bile is unlikely to lead to any change in the gall-bladder by direct passage.

Although the belief that the organisms were excreted by the liver into the bile, and thus infected the gall-bladder, was fascinating in that it was known that the liver had an inhibitory action upon organisms, and thus a chronic infection of the gall-bladder—which alone can give rise to gall-stones—would be more likely to be caused, yet many of the above observations seem to prove that infection from the bile itself is unlikely even by this path; moreover, such a means of infection would in no way explain the usual absence of cholangitis.

To-day, therefore, the general opinion is that the infection of the gall-bladder itself occurs either as a systemic infection or by direct or lymphatic spread from the gall-bladder or appendix. I have never been satisfied that sufficient evidence has been brought forward of a really close relationship between appendicitis and cholecystitis. That the two conditions can occur together is undoubted, but in my experience this has been relatively rare—that is to say, by no means as frequent as is commonly stated. In many cases of an operation upon the gall-bladder the appendix has been found to show some fibrosis or a few adhesions; which fact has been accepted—in my opinion unjustifiably—as evidence of a past appendicitis. That the primary infection is in the gall-bladder wall can, I think, be accepted to-day as true in the vast majority of cases. The experimental work of Illingworth and Wilkie showing that the bile inhibits the growth of organisms, that in cases of cholecystitis it is often sterile, that organisms—usually streptococci—are found in the substance of the gall-bladder wall and that these organisms when injected into the lumen of the gall-bladder produce no change, whereas when they are injected into the substance of the wall they generally produce a cholecystitis, appear to make this quite definite. Graham has shown that in most cases of cholecystitis there is an adjacent hepatitis suggesting that the primary infection might have been of the liver and thence passed by direct or lymphatic spread to the gall-bladder wall. It could, however, be argued equally well that the infection had spread from the gall-bladder to the liver—a path which I think is more probable, in that the liver changes are always most marked in the immediate vicinity of the gall-bladder. The long-standing work of Rosenow, showing that cholecystitis could be produced by the injection of specific organisms into the blood stream, and Mann's interesting observation that an acute cholecystitis rapidly followed the injection of Dakin's solution into the blood stream, strongly suggest that the infection is through the systemic blood stream. Many clinicafacts support these views. It has been known for years that cholecystitis might follow influenzal and pneumonic infections and that the organisms of these diseases might be found in the gall-bladder.

Some years ago I was impressed with the frequency with which gall-bladder changes were associated with urinary symptoms. Of the series of 347 cases I examined, 73, or 21 per cent., showed such symptoms, and of a smaller series in which the urine was specially examined *B. coli* was found in 75 per cent. Even at this time clinical facts, therefore, seemed to support the view that a cholecystitis was only the later result of a mild general septicæmia, usually due to the *B. coli* group of organisms. Of late years it is becoming widely appreciated that gall-bladder symptoms, especially in their early stages, are often associated with other evidence of general infection. They may occur with osteo-arthritis, tonsillitis, dental sepsis, and gastro-intestinal disturbances. Evidence, therefore, that a cholecystitis is only a part of or the late result of a mild general septicæmia appears to be very strong, the great point of interest being that whereas a few years ago the indications were that such infections were most commonly of the *B. coli* or typhoid group, to-day they seem more generally to be the late results of a chronic streptococcal infection.

RECURRENCE OF CALCULI.

This modern evidence in support of the view that chronic cholecystitis is inflammatory in origin and is the late expression of a mild general septicæmia throws light upon the interesting questions of the important bearing of foreign bodies in the gall-bladder and the formation of recurrent calculi. The importance of foreign bodies within the lumen of the bladder has been recognised for many years, and it has even been believed that the dead bodies of micro-organisms formed the centre of every calculus. The evidence of this is uncertain, but it is clearly proved that any unabsorbable suture may act as a focus for the formation of calculi. In the olden days when cholecystostomy was a routine operation, a silk suture used occasionally to be used for fixing in the drainage-tube. Several cases have been reported where at a later period there was evidence of the reformation of calculi, and at a second operation a calculous mass was found around the suture. One such case occurred in my series, and in the specimen it is evident that the calculous material is formed around a looped suture. This method of formation of stones was first reported by Homans and confirmed by the experimental work of Mignot, but since that time many other examples have been reported. It is interesting to note in the light of our modern knowledge that the majority of such sutures were in the substance of the gall-bladder wall, and probably did not project into the lumen. Nevertheless, in Mignot's experiments the suture was placed actually in the cavity of the gall-bladder. Clinically his experiments have to a certain extent been reproduced by Nature, in that cases have been reported where a round worm has crawled up the cystic duct into the cavity of the gall-bladder and the dead body has formed the nucleus of a calculus.

Recurrent calculi in a few cases may actually be formed in the ducts. The best example of such a true recurrence is in the case of acholuric jaundice, where the gall-bladder has been drained or removed and the spleen left untouched. They may also occur if there has been a definite cholangitis. In both these cases the calculi are formed of pure pigment-calcium and not uncommonly form a soft putty-like mass. The greater number of clinical recurrences are either due to stones having been overlooked at the first operation, either in the bladder or ducts, or to a true reformation in the gall-bladder. Stones may easily be overlooked even in the gall-bladder itself if it be acutely inflamed; much more readily does this happen in an abnormally long cystic duct or in the common duct if the gall-bladder be drained or even removed without exploration of the ducts. My own experience has been that stones may occur in the common duct and yet give rise to none of the characteristic symptoms. In my own series of 95 common duct stones there were 29 which were unassociated with jaundice. Nor is it always possible to feel the stones from without. I have not uncommonly found a duct which has appeared perfectly normal upon external palpation, but upon the introduction of a pair of forceps a calculus has been removed. If a cholecystostomy be performed, a routine exploration of the duct can only be carried out by making a separate incision into the common duct, a step which would often appear to be unjustifiable. Overlooked stones which have remained in the common duct or in the stump of the cystic duct can be distinguished from true recurring calculi by the fact that they generally contain some cholesterol as an indication that they were formed within the gall-bladder. True recurring stones in the gall-bladder are usually of the same structure as those removed at the first operation, and therefore it may be impossible to say with certainty whether they were overlooked at the first operation or have been formed since. They form much the higher proportion of so-called recurring calculi. In my own 28 cases of recurrence 22 occurred in the gall-bladder after cholecystostomy; of these, 4 took place in a total of 51 cholecystostomies which I had performed myself, this giving a recurrence-rate of nearly 6 per cent.—a further indication that the formation of calculi is dependent upon the presence of an inflamed gall-bladder and not, as a rule, upon any metabolic error. The removal of the gall-bladder would seem to be clearly indicated as the routine operation, not only because it alone gets rid of the seat of the chronic inflammation, but it allows an easy routine examination of the bile-duct so that calculi are less likely to be overlooked.

SYMPTOMATOLOGY.

It is unnecessary to-day to point out that colic or jaundice or the presence of suppuration in the gall-bladder are not the symptoms of gall-stones but of their complications, and therefore do not enter into our present discussion.

It is now being realised that in the early stages the symptoms are often only a part of some general septic infection. The association of cholecystitis with a general chronic arthritis has been discussed by Wilkie and is to-day well recognised. In other cases there is either a past history of frequent attacks of sepsis of the tonsil or of the mouth and teeth, or indeed the patient may be actually under treatment with these conditions. I have seen a considerable number of cases of late in which patients have been under treatment for several weeks with mild attacks of pyrexia, a general feeling of malaise, evidences of dental and tonsillar sepsis, and later have developed dyspeptic symptoms and then pain and tenderness localised over the gall-bladder. The frequency with which cholecystitis has a history of onset after a certain pregnancy, and especially one associated with a *B. coli* infection, has already been mentioned, but to-day it seems more common for the symptoms to follow what is usually described as an influenzal attack.

Even when the infection is localised to the gall-bladder the symptoms in the earlier stages are ill-defined and likely to be overlooked. They consist of general dyspeptic disturbances, which at first may consist of a feeling of fullness, nausea, and vomiting, and a loss of appetite, but shortly after onset there is a distinct pain which commences in the epigastrium, passes to the right hypochondrium, and is associated with deep tenderness over the liver and gall-bladder. It is probable that at this period there is a catarrhal cholecystitis. Later the symptoms become more localised, the pyrexia tends to disappear, and the patient is left with a characteristic dyspepsia of cholecystitis. This shows itself as a feeling of fullness and distension after meals, which persists day by day without any intermission. The discomfort occurs immediately after meals or even before the meal is completed. It is often associated with a persistent occipital headache. During this more prolonged period exacerbations of the general or local infection are likely to occur, so that there may be pyrexial attacks of unknown origin associated with an increase of the general malaise. If the inflammation be more localised there will be an increase of the pain and tenderness in the gall-bladder area, and with each attack the characteristic gall-bladder hyperæsthesia may be evident. The cause of the dyspeptic symptoms during this period is but ill-understood. It is natural to suppose that the symptoms are dependent upon the contractions of a diseased gall-bladder which probably occur during or shortly after the ingestion of food. The complicated experimental work tending to show that the gall-bladder has no inherent power of contraction does not negative this supposition, for with the introduction of cholecystography it has been made quite evident that the partaking of certain foods, especially fat and yolk of egg, will cause emptying of the gall-bladder (Boydon). It has, however, been my experience that a large number of patients have continued to suffer from this flatulent dyspepsia for some weeks, or sometimes even for two or three months, after removal of the gall-bladder, and the fact that some 40 per cent. of cases of chronic cholecystitis have an absence of free acid in their test-meals would make it evident that they are the subjects of a chronic gastritis which possibly may be a relic of a general infection and which tends to persist for a short time after removal of the gall-bladder.

FINDINGS AT OPERATION.

The pathology of the gall-bladder in this stage of the disease is of considerable interest. If the condition be operated upon during an exacerbation, the gall-bladder, instead of presenting the characteristic deep blue appearance due to the bile shining through the thin wall, is seen to be thick, opaque, and œdematous. One or more enlarged lymph glands may be felt adjacent to the cystic duct, but according to Baumgartner, in 40 per cent. there are no stones. It is very probable that this condition is purely catarrhal and may heal between the attacks. It is evident, therefore, that the treatment should not be surgical unless there is very definite evidence that the change is not only recurrent but is maintaining the general infection. In other cases the typical "strawberry" gall-bladder may be present. This is very difficult to diagnose from the external appearance. Like the last group, the gall-bladder wall is thick and opaque and may show an œdema and enlargement of the lymphatic glands. More commonly, however, there is some early fibrosis, so that the gall-bladder wall is already harder and thicker than normal, and may show some distortion. As only 50 per cent. of this variety are associated with gall-stones, the absence of calculi cannot be taken as evidence that the gall-bladder is normal. In the later stages there may be distinct fibrosis with the formation of stones, the condition passing on to that of the well-known chronic cholecystitis. Since in the early stages the changes are so ill-defined, it is important to recognise the evidence which at operation may be accepted as warranting a diagnosis of cholecystitis. If stones are present, the nature of the lesion is, of course, evident. In my experience a gall-bladder which is not acutely inflamed or whose ducts are not completely obstructed can always be emptied by gentle pressure and the stones therefore palpated. Since, however, calculi are absent in a large number of these early cases, reliance will have to be placed upon other changes. In order of importance I would place these as: (1) changes in colour; (2) thickening from fibrosis or œdema; (3) the presence of enlarged glands; and (4) fibrosis of the adjacent liver. Of this latter change I am not nearly so confident as others appear to be. That a certain amount of fibrosis of the liver is very common in chronic cholecystitis is a fact accepted by all, but I am certain that a similar change may be found where there is a Riedel's lobe to the liver and where the liver has dropped as a whole.

A consideration of these pathological changes will make it evident that a clinical diagnosis at this stage is far from being easy. In the early periods the problem before us is that we have a patient suffering from prolonged and relapsing septic infection, the primary source of which it is very often difficult to locate, and a careful examination of the tonsils, teeth, and accessory nasal sinuses is generally required before the gall-bladder can be considered as the seat of infection. When the dyspeptic symptoms dominate the clinical picture, the diagnosis from a chronic gastritis, from visceroptosis, and from chronic pancreatitis may be associated with considerable difficulty. At one time it was thought that the Meltzer-Lyon test would be very helpful in these cases, but in my own relatively small experience it has been of very little help. Undoubtedly to-day the greatest help is obtained by cholecystography, but, as with all valuable means of investigation, there is some danger that too much reliance may be placed upon this method. When it is remembered that this test is dependent upon the fact that a dye which is opaque to the X rays is excreted by the liver into the bile, and that the bile containing it is concentrated to a marked degree by the normally functioning gall-bladder, it will be realised that in this country, where the dye is nearly always administered by mouth, a shadow of the normal gall-bladder indicates that the dye is being adequately absorbed from the intestine, that it is being normally secreted by the liver, that the liver secretions are passing freely into the gall-bladder, and that the gall-bladder is adequately concentrating the bile. An error in any one of these steps would lead to an absence of the normal gall-bladder shadow, and hence the absence of the shadow alone must not be regarded as definite evidence that the function of the gall-bladder is at fault. In the same way irregularities of outline do not of necessity mean a chronic inflammation of the gall-bladder. Alterations in its shape due to congenital deformities or to the presence of congenital cystico-colic or cystico-duodenal bands, which are of little or no clinical importance, are well recognised and may be a source of fallacy. I am confident that to-day far too many gall-bladders are being operated upon simply because there is an absence of the normal shadow or because the gall-bladder shows some irregularity in outline.

TREATMENT.

The diagnosis of gall-bladder lesions has now reached the stage which gastric lesions occupied a few years ago, and there is a tendency to advocate operation as soon as any inflammatory change or an error of function is recognised. As with early lesions of the stomach and duodenum, it must be remembered that although distinct changes may be diagnosed and their presence confirmed by cholecystography, they may still be curable by medical treatment. That some of these milder degrees of cholecystitis may be so cured is beyond question. Whether the lipoid deposits causing a typical "strawberry" gall-bladder can also be cured without operation is less certain, but my own belief is that operative treatment should only be considered in these early stages if adequate relief is not gained by medical measures. If the symptoms of general infection do not abate, or if they frequently recur, if there is marked tenderness over the gall-bladder, and if these symptoms are associated with distinct evidence of an alteration in the functioning of the gall-bladder, then an operation should be undertaken. On the other hand, once there is evidence that stones are present, either owing to the presence of attacks of colic or to a positive appearance of calculi on a simple X ray plate, or as negative shadows after cholecystography, I am sure that operative treatment will be required sooner or later.

The evidence I have put before you as to the method of formation of calculi is, to my mind, convincing that when once they are present they can never be dissolved, nor have I ever been able to obtain evidence that a patient once having had calculi has been able to pass them and to be cured of the underlying gall-bladder trouble. It is therefore far better to operate in this stage where there is only a mild cholecystitis, rather than to await the onset of severe and often dangerous complications.

The actual technical details of the operation will become evident from the pathological considerations I have put before you. Some years ago it was the custom, if the gall-bladder appeared but slightly changed, to remove the stones and to drain the viscus in the belief that the inflammatory changes would disappear, cholecystectomy being reserved only for the more advanced stages of the disease. When once it is accepted that the presence of stones is due to inflammatory changes, and that these changes are dependent upon a blood-borne infection which is carried to the wall of the gall-bladder, it will be evident that a cure by draining of the viscus is most improbable, and indeed the frequency with which the recurrence of calculi is found after simple cholecystostomy supports this view. We may say, therefore, that the ideal operation, both from theoretical and practical knowledge, is a cholecystectomy. Unquestionably this is an operation requiring greater care and technical knowledge than a cholecystostomy, but if it be accepted as an axiom that no duct be ever divided until the cystic, common, and hepatic ducts are all exposed, the danger of any operative accident is very greatly lessened. Since it is difficult, if indeed not impossible, to eliminate the presence of stones in the common duct by means of the clinical history or by means of external palpation, the common duct, wherever possible, should be explored through the stump of the cystic duct. My own view is that this step should also be followed by dilatation of the ampulla, so that there is a free passage of the bile into the duodenum. This, then, I would regard as the ideal operation, but in some cases it may not be possible. With very stout patients and those suffering from any severe complications, the carrying out of the whole of this procedure may be associated with very considerable risk to life, which is greater than that of overlooking stones in an unexplored common duct. In patients who are suffering with an acute or even gangrenous cholecystitis, the general condition may be so bad that the surgeon has to be satisfied with a cholecystostomy, although it is almost certain that a more radical operation may be required at a later date. The first consideration in such conditions must always be the safety of the patient.

Whatever operative steps have been performed, I am strongly of the opinion that it is always wise to insert a drainage-tube down to the cystic duct for a few days; however carefully the stump of the cystic duct be sutured a certain amount of leakage of bile may take place. There is no doubt that this not uncommonly occurs from small bile-ducts opening into the gall-bladder bed, and therefore is not dependent upon carelessness in the closure of the cystic duct. Should there be no tube a considerable amount of irritation or even an abscess may later arise. If the progress is uninterrupted it may be removed in two or three days; it has never in my experience led to the slightest disability, and can safely be used as a routine step.

SUMMARY.

I would briefly summarise these views by stating that: (1) cholelithiasis is, in the majority of cases, dependent upon inflammation of the gall-bladder; (2) this inflammation is due to a blood-borne infection; (3) it is at first a part of a general infection or mild septicæmia; (4) in the early stages of cholecystitis medical treatment should always be attempted; (5) when once stones have been formed surgical interference should always be sought; (6) the ideal surgical treatment consists of cholecystectomy, exploration of the common duct, and dilatation of the ampulla.

A STUDY OF
CALCIUM METABOLISM IN THE ACUTE STAGES OF CHOREA IN CHILDREN.*

BY E. C. WARNER, M.D., B.Sc.,
M.R.C.P. LOND.,
PHYSICIAN IN CHARGE OF THE CHILDREN'S DEPARTMENT, THE MILLER GENERAL HOSPITAL, AND MEDICAL REGISTRAR, GUY'S HOSPITAL.

(From the Departments of Physiology and Pharmacology, Guy's Hospital.)

FOR many years it has been remarked that there is a certain type of child who is especially liable to rheumatism. This has been expressed as a "rheumatic diathesis." In the absence of definite evidence of the nature of the infecting agent, the most satisfactory method of attacking the cause of the disease seems to lie in investigation of the underlying metabolic condition. The presence of such an underlying condition is generally accepted as the only way of explaining some of the peculiar features of this disease—e.g., its extreme frequency in the poorer and its absence in the better classes of the populace, and also its relation to climate.

It has been shown that in chorea there is an increased electrical excitability of the neuro-muscular junction during the active stages of the disease, and that this gradually passes off as recovery ensues.[1] It therefore seemed advisable to study the relationship of these results to the calcium metabolism of the children. The part played by calcium in regulating the excitability of nerves and muscles has been studied in experiments on animals and also in human beings; some of the more important results are as follows.

Animal Experiments.

Biedermann[2] first showed in 1880 that a curarised sartorius muscle in a sodium salt solution free of calcium shows increased irritability and undergoes rhythmical contraction. Loeb[3] demonstrated the same phenomenon with an isotonic sodium salt solution, and showed that it was prevented by adding 10 mg. of calcium per cent. He concluded "that we are indebted to the calcium in our blood to prevent our muscles constantly twitching." Keith Lucas[4] showed that the minimal stimulus required to produce excitation of a nerve increases in proportion to the amount of calcium in the solution bathing it. Again, if blood from a parathyroidectomised animal be perfused through the leg of a normal animal, it produces a rise in the excitability of the muscle. This excitability is diminished by adding calcium.[5] After removal of the parathyroids in a dog, there is a fall in the serum calcium from 10–12 mg. per cent. to 5–8 mg. per cent., and the resulting tetany is relieved *temporarily* by intravenous injections of calcium.

Results in Man.

Howland and Marriott[6] showed that in active infantile tetany the muscles responded to an electrical stimulus obtained with the cathode opening current (C.O.C.) of less than 5 milliampères; after recovery the C.O.C. has to be greater than 5 milliampères to produce a response. At the same time they showed that in active tetany the average value of the serum calcium was 5·6 mg. per cent., as compared with a value after recovery of 10·2–11·0 mg. per cent.

This is sufficient to prove the profound effect that a lack of calcium produces in increasing the electrical excitability of muscles and nerves. The question naturally arises of how far the increased electrical excitability met with in chorea is related to a calcium deficiency. The calcium in the blood is almost entirely present in the serum and the plasma, the cells containing but a small fraction of the total blood calcium.[7] That part of the blood which comes into contact with the tissues is the plasma, and so it is the calcium content of plasma which should be measured. The serum calcium is directly proportional to the plasma calcium, although giving slightly lower values,[7] and it is much more convenient to measure the serum content, as most methods for preventing coagulation depend upon precipitation or alteration of the state of the calcium (as by sodium oxalate and sodium citrate).

---

* Part of thesis approved for the Degree of Doctor of Medicine by the University of London. Part of this work was done during the tenure of the Parson's Research Fellowship at Guy's Hospital, and subsequently with the aid of a grant from the British Medical Association.

The calcium in the serum is present in at least two forms: (*a*) That fixed by protein. The amount present in this form is directly proportional to the amount of protein present,[8] and is rendered inactive by its combination with protein. (*b*) Inorganic calcium. This is largely present as phosphate and bicarbonate, and is of special importance as it gives rise to the active calcium ions of the blood. Marrack and Thacker [9] believe that all the inorganic calcium of the blood is ionised, but Percival and Stewart [7] and Brinkman and van Dam [10] believe that only part is ionised. Whichever view is correct, the amount of ionic calcium present is certainly in proportion to the amount of inorganic calcium. It is therefore important to study not only the total serum calcium, but especially the inorganic calcium of the blood. The inorganic calcium can be separated from the blood by dialysis in vivo, as has been performed by Percival and Stewart [7] through the living peritoneal membrane, or in vitro through a collodion membrane (D. J. de Waard,[11] Cushny,[12] Walpole [13]). There is always the danger that the state of the calcium may be altered during the time (which amounts to a matter of hours) that the dialysis is occurring. When working on human beings, Marrack and Thacker proved that the amount of calcium present in an inorganic form in the serum is the same as that present in normal cerebro-spinal fluid.

The results obtained by these different observers may be summarised thus (Table I.).

TABLE I.

Inorganic Calcium of Blood.

—	Mg. per cent.	Method.
Percival and Stewart	6·4 7·4	In vivo dialysis in cats under anæsthesia. Collodion membrane in man.
Marrack and Thacker	5·8	In vitro dialysis through collodion membrane in man.

Cerebro-spinal Fluid.

—	Mg. per cent.		Method.
Matsuhashi [14] ..	5·2	—	Unanæsthetised dogs.
	Average.	Range.	
Neale and Esslemont [15]	5·7	5·1–6·5	Non-meningitis cases without convulsions.
Neustaedter [16] ..	5·8	—	Normal men and children.

It is important to note that the calcium content of the cerebro-spinal fluid is not affected by repeated lumbar puncture.[17] Matsuhashi showed that after removal of the parathyroids and part of the thyroid in dogs the cerebro-spinal calcium fell from 5·2 to 4·2 mg. per cent., coincident with the onset of tetany.

Methods in this Investigation.

The method of estimating the calcium in the present investigation has been that of Bainbridge and Trevan,[18] which gives reliable results to within ± 0·10 mg. per cent. For each estimation only 1 c.cm. of fluid is needed; two or three determinations have been made wherever possible and the results averaged.

The method consists in the precipitation of the calcium by saturated ammonium oxalate and then washing the calcium oxalate precipitate twice with a saturated solution of ammonium oxalate. The calcium oxalate is dried and heated and so converted into the carbonate. The amount of this is estimated by dissolving in an excess of N/100 phosphoric acid and backward titrating the excess of acid with N/100 sodium hydrate to an end-point of pH 3·97* (indicator brom-phenol blue).

There are several precautions to be adopted.

(*a*) Firstly it is essential to separate the serum from the blood soon after it is shed, otherwise the serum calcium value falls fairly rapidly. Apparently the calcium goes into the clot. The effect of allowing the serum to stand in contact with the clot is shown in Table II.

TABLE II.

		Mg. per cent.
Serum obtained	Immediately after drawing blood ..	10·99
	After leaving clot with serum for 12 hours in ice-chest	10·40
	After leaving clot with serum for four days in ice-chest	9·06

If the serum is separated immediately, and it or the cerebro-spinal fluid stored in an ice-chest, the calcium content remains practically constant (Table III.).

TABLE III.

	Mg. per cent.
Cerebro-spinal fluid calcium content	5·43
Ditto after 27 days in ice-chest	5·33
Blood-serum calcium content	8·68
Ditto after standing in room for 5 days	8·69

(*b*) Secondly, at least 16 hours must be allowed for complete precipitation of the calcium as oxalate. In this series of estimations 24 hours have elapsed in every case.[7] It seems very probable that the neglect of these precautions accounts for many of the anomalous results of calcium estimations recorded in the literature.

Results.

Total Serum Calcium.—The total serum calcium varies with the method used. Many observers have not allowed complete precipitation to occur, and so have obtained low values. The results obtained in this series are summarised in Table IV.

TABLE IV.

Cases.	Average age in years.	No. of cases.	Serum calcium in mg. per cent.	
			Average.	Range.
Severe chorea ..	10	15	9·66	8·68–10·21 (+1 case 11·18)*
Mild chorea ..	8	9	9·79	9·36–10·37
Recovered cases of chorea ..	9	14	10·14	9·12–10·89
Healthy medical students ..	17	6	10·49	9·66–11·50
Convalescent cases of bone disease	14	12	10·01	9·40–10·74

* This case subsided in two weeks without treatment.

TABLE V.

Case.	Serum calcium in mg. per cent.		
	During active chorea.	After chorea subsided.	Time after active chorea and treatment stopped.
1	9·10	10·24	6 weeks
2	9·42	9·70	9 months
3	9·70	10·41	10 weeks
4	8·84	9·69	3 months
5	10·21	10·63	2 ,,
6	11·18	10·19	4 ,,
Aver.	9·74	10·14	—

The control really required is a series of middle-class children of the same age, as it appears possible from Table IV. that all poor children have a low value for the serum calcium, especially as Howland and

---

* This was chosen as a convenient end-point as it is the pH of a N/20 solution of potassium hydrogen phthalate. If kept in a paraffined bottle the pH of the solution remains constant for three weeks.

Kramer[19] found distinctly higher values in children than in adults. The values in the children during active chorea and again after recovery are shown in Table V.

Tables IV. and V. show that the serum calcium rises as recovery occurs, the rise being on an average 0·48 (Table IV.) and 0·40 (Table V.) mg. per cent.

Calcium Content of Cerebro-spinal Fluid.—It is important to obtain the normal figure before proceeding to estimate the value in cases of chorea. It is extremely difficult to get samples of cerebro-spinal fluid from perfectly normal children, and the nearest approximation is to use pathological fluids of low protein content from a large variety of cases. The values are shown in Table VI.

TABLE VI.

Case.	C.S.F. calcium in mg. per cent.	Disease.
11	5·43	Tuberculous meningitis.
12	4·54	
13	5·55	
14	5·17	
15	5·83	Specific encephalitis.
16	4·89	Juvenile taboparesis.
17	5·81	Meningococcal meningitis.
18	5·32	Mental deficiency.
19	5·53	Recent poliomyelitis.
Average	5·34	—

These values approximate to the results of other workers. Neale and Esslemont[15] found an average value of 5·7 mg. per cent. (range 5·1 to 6·5 mg. per cent.) in a series of non-meningitic pathological fluids; and Neustaedter[16] obtained an average value of 5·8 mg. per cent. for normal men and children.

In the cases of chorea the following values have been obtained (Table VII.).

TABLE VII.

—	No. of cases.	Calcium content of cerebro-spinal fluid in mg. per cent.	
		Average.	Range.
Severe chorea	18	4·61	4·36–4·75
Recovered cases of severe chorea (within 6 months of recovery)	7	5·18	4·87–5·48
Mild chorea	3	5·04	4·86–5·40

N.B.—In most cases the samples were obtained by lumbar puncture under local anæsthesia. Occasionally, with a severe case, a short general anæsthetic with ethyl chloride had to be administered.

From this it is seen that the values in cases of severe chorea are all subnormal and that they rise by an average of 0·59 mg. per cent. (=12·8 per cent.) when recovery occurs.

The values obtained in a series of cases studied during the stages of severe active chorea and again after recovery are shown in Table VIII.

TABLE VIII.

Case.	C.S.F. calcium in mg. per cent.		Time after recovery and treatment stopped.
	Severe active chorea.	After recovery.	
6	4·75	5·43	4 months
5	4·72	5·31	2 ,,
7	4·70	5·04	6 weeks
1	4·53	4·87	4 ,,
8	4·43	5·48	4 ,,
9	4·69	5·15	10 ,,
20	4·67	4·96	6 ,,
Average	4·64	5·18	—
Range	4·43–4·75	4·87–5·48	—

There is evidently a rise in the average calcium when the chorea subsides, to the extent of 13 per cent. of the value during active chorea. The ultimate values in the series shown in Tables VII. and VIII. are still a little lower than the average figure obtained from a series of pathological samples of cerebro-spinal fluid. This may well be related to the rather short time elapsing between the subsidence of chorea and the taking of the final sample.

Perhaps the most striking relationship is shown by following the cases through and comparing the values obtained in the active phase and during the subsidence of the disease (Table IX.).

TABLE IX.

Case.	Date.	C.S.F. calcium in mg. per cent.	Remarks.
10	July 8	4·71	Severe chorea.
	Aug. 3	4·62	No improvement.
	Sept. 9	5·74	Free of chorea.
9	April 30	4·69	Severe chorea.
	June 13	4·85	Slight improvement.
	July 11	5·15	Free of chorea.
5	June 13	4·62	Severe chorea.
	July 22	5·05	Very slight chorea.
	Sept. 19	5·31	Free of chorea.

In many of these children Dr. A. A. Osman and Dr. H. G. Close have been kind enough to estimate the alkali reserve of the blood plasma by their modification[30] of the method of van Slyke, Stillman, and Cullen.[31] The results are shown in Table X.

TABLE X.

—	No. of cases.	Average age.	Plasma $NaHCO_3$ expressed in terms of molecular concentration.	
			Average	Range.
Severe chorea ..	6	13	0·0291	0·0271–0·0323
Mild chorea ..	7	11	0·0295	0·0258–0·0323
Recovered chorea ..	4	11	0·0298	0·0289–0·0322
Normal controls (non-rheumatic children of the hospital class of patient) ..	38	9	0·0290	0·0265–0·0320

In two cases Dr. A. C. Hampson has determined the pH of the blood plasma with the glass electrode, and in both cases a normal figure was obtained. This shows that the acid-base equilibrium of the blood plasma is normal in choreic children, just as it is in rheumatic children.[32]

Summary of Results and Conclusions.

In chorea there is a rather low value in the total serum calcium, which rises as the chorea subsides. The ultimate value reached is similar to those obtained in control cases of convalescent bone disease, both groups of case being drawn from the poorer classes of the population. These are lower than the values obtained in six healthy medical students of the age of 17. If the results of Howland and Kramer are confirmed and it is found that children should have higher values than adults, all children in poor circumstances may apparently have low values, and this fact may well be related to poverty and the debility associated with it. This is not at all unlikely; in the rapidly growing infant, where calcium is needed in the greatest quantity for bone formation, rickets is very common and infantile tetany is frequently associated with it.

The calcium content of the cerebro-spinal fluid in chorea is consistently low, and at the same time there is a rise in the electrical excitability of the peripheral nerves and muscles as measured at the "motor point." As recovery ensues, corresponding with the rise in the calcium of the cerebro-spinal fluid, the electrical excitability diminishes.[1]

The calcium content of the cerebro-spinal fluid is important from two points of view. In the first place, the calcium content of the cerebro-spinal fluid is, according to Marrack and Thacker, equivalent to the inorganic calcium content of the blood. The low values met with in chorea indicate that all the tissues of the body, including the brain, are supplied by a fluid deficient in inorganic calcium, and therefore in calcium ions. In the second place, the cerebro-spinal fluid is one of the main sources of nutriment to the brain and its cells. Surrounding the nerve-cells are perineural spaces, continuous with the perivascular spaces and containing cerebro-spinal fluid, as was demonstrated by Mott[20] and confirmed later by Weed.[21] The nerve-cells in cases of chorea are therefore bathed by a fluid which is 13–15 per cent. deficient in calcium. This in itself is sufficient to raise the excitability of the nerve-cells, in the same way that deficiency in calcium is known to raise the excitability of the peripheral neuromuscular apparatus. Moreover, Sabbatini[22] showed that the direct application to the surface of the brain of salts which produce precipitation of calcium causes an increased excitability of the cerebral cortex.

These results have a considerable bearing on the subject of chorea in children, and may well help in the elucidation of this disease, which the pathological findings do not in themselves always seem capable of explaining. Poynton and Holmes,[23] who described the autopsy findings, showed congestion of some parts of the brain with degeneration of some cortical nerve-cells. But recently Bernard Shaw,[24] in a very careful examination of the brain of a case of chorea, concluded that "no adequate anatomical basis for the chorea is found in the meninges, cerebral cortex, caudate nucleus, corpus striatum, optic thalamus, mesencephalon, and pons. All these showed hyperæmia, but no vascular or inflammatory lesions." If chorea were solely due to a bacterial invasion of the brain, evidence of this should be shown by an abnormality either of the protein or the cells contained in the cerebro-spinal fluid. These have been examined in a few cases in this series, and have always been found to be normal. This is in agreement with the findings of Levinson[25] in his series of cases, while Morse and Floyd[26] found a slight increase in the number of cells as the only abnormality in 3 out of 19 cases.

The presence of this calcium deficiency may help to explain some of the characteristic features of chorea. Chorea is met with during the period of growth, when there is a special need of calcium in all the tissues of the body. After the age of 25, when ossification ceases, chorea is very rarely seen except during pregnancy, when again there is a drain on the calcium reserves of the body in order to supply the fœtus. Also, just as rickets is largely confined to the poorer classes at an early age, so is chorea at a later age. It may be that, just as rickets is associated with faulty calcium metabolism at an early age, so is chorea at a later age. This is not in any way denying that there is an infection associated with chorea and acute rheumatism, for this infection must almost certainly be the explanation of the valvular lesions in the heart. But it does seem probable that the nervous, restless, over-active child, with its long period of debility preceding the signs of infection,[27 28] may be suffering from a calcium deficiency which itself may be accentuated by the infection. This is parallel with the low state of health associated with rickets, and it is well known that rickety children are very prone to infective disorders. This hypothesis can only be confirmed by further work, but it is in keeping with the results of Thompson and Leighton,[29] who showed that a chronic parathyroid deficiency, due to ligature of the vessels of the parathyroids, produces a progressive loss of weight and diminished resistance to infection. The cause of the calcium deficiency met with in chorea and its relationship to the treatment of chorea are still under investigation.

In conclusion, I should like to thank the following for permission to investigate cases under their care: Dr. E. P. Poulton, Dr. N. Mutch, Dr. J. A. Ryle, Dr. H. C. Cameron, Dr. J. M. Campbell, and Dr. A. H. Douthwaite at Guy's Hospital; Dr. M. Davidson at the Miller Hospital; Dr. A. C. Hampson and Dr. A. A. Osman at Queen Mary's Hospital, Stratford; and Dr. W. T. Pugh and Dr. N. Gray-Hill at Queen Mary's Hospital, Carshalton.

A PERNICIOUS TYPE OF ANÆMIA FOLLOWING ERYTHRÆMIA.

By HAROLD AVERY, M.B., M.R.C.P. Lond.,
MEDICAL REGISTRAR, CHARING CROSS HOSPITAL, LONDON.

THE association of various forms of blood disease and the change from one to another have been described by many writers. Excessive activity of the myeloid common stem cell, the hæmocytoblast, results in the flooding of the peripheral blood with its derivatives; polycythæmia follows over-activity of the erythropoietic function; myeloid leukæmia from over-activity of granulocytopoiesis. When stimulation of both functions (pan-myelosis) occurs, with a resulting blood picture of a mixed erythræmia and myeloid leukæmia, the condition is known as erythro-leukæmia,[1–5] or subleukæmic erythræmia.[6] Cases have also been described in which erythræmia has supervened in myeloid leukæmia,[7–9] and others in which the reverse has occurred.[10–16] A similar reaction of both erythro- and granulo-poietic tissues is sometimes seen in pernicious anæmia when the differential leucocyte count has the characteristics of myeloid leukæmia; this has been termed "leukanæmia."[17] The appearance of large numbers of megacaryocytes in the peripheral blood with a great increase in their derivatives, the blood-platelets, may be the essential feature of a myelosis known as "piastrinæmia."[18–20]

Freund,[21] in 1919, was the first to describe the transformation of established polycythæmia of many years' standing into an anæmia closely resembling pernicious anæmia. Minot and Buckman[14] described three further cases in 1923, and Delhougne, Gotschlich, and Froboese[22] recorded two cases in 1928. As no case has been described in this country, the following one, which I observed over a period of five years, and then examined post mortem, is of interest.

Clinical History.

A stonemason, aged 60, was admitted into Charing Cross Hospital under the care of Dr. W. J. Fenton, in June, 1923, complaining of general debility, breathlessness on exertion, giddiness, and attacks of vomiting of about six months' duration. There was nothing of note in the past and family history. The complexion and tongue were of a purple hue, the spleen was not palpable, the heart was not enlarged, a right inguinal hernia was present, the blood pressure was 160 mm. Hg systolic and 100 mm. Hg diastolic. The blood count showed 7,300,000 red cells per c.mm. (for details see Table). After ten weeks as an in-patient, during which time a radical cure of the hernia was performed, the patient was sent to a convalescent home, and then reported fortnightly.

In November, 1923, he complained of pain in the left hypochondrium and the presence of a "lump"; on examination a tender spleen could be felt extending three fingers-breadth below the costal margin. The enlargement continued until the spleen reached across the middle line below the umbilicus. There were occasional complaints of pain over the spleen, "as if the stomach was on the boil," most marked on pressure or stooping; these attacks coincided with tenderness of the spleen, but not with any noticeable alteration in either the size of the spleen or the blood count. Sleeplessness became a marked symptom, and several attacks of bronchitis occurred. Treatment was symptomatic and venesection was frequently performed.

In July, 1925, œdema in the legs first began to appear, and from November, 1926, the patient began to suffer from attacks of gout, the right fifth metatarso-phalangeal joint being the most frequently attacked; colchicum and atophan (grs. 4, b.d.s. on alternate days) gave great relief. In June, 1927, there was an attack of herpes over the upper part of the left ear.

In April, 1928, there was a complete change in the clinical picture; instead of the purple appearance of the polycythæmic, the lemon yellow tint of pernicious anæmia was present. The patient complained of feeling very weak, of swelling of the feet, of increased shortness of breath, and of loss of weight. The tongue was glazed, cracked, and sore; the spleen was enlarged to 1½ in. below and to the right of the umbilicus; the lower border of the liver was felt two fingers-breadth below the right costal margin; the heart was not enlarged. The blood pressure was 140 mm. Hg systolic and 110 mm. Hg diastolic. A blood count showed: red cells, 2,100,000; hæmoglobin, 44 per cent.; colour-index, 1·01 (for further details see Table). Soon after admission into hospital pain appeared in the right chest, and a pleural effusion rapidly developed which I replaced by air; but it soon reaccumulated. The fluid contained 99·67 per cent. of lymphocytes, no tubercle bacilli were seen, and cultures were sterile. The van den Bergh test gave a slight positive indirect reaction, urobilin in the stools was increased, and the blood-cholesterol content was reduced to 0·07 per cent.

Treatment with liver diet was carried out, half a pound of liver being given daily either in soup, fried, baked, spiced raw liver sandwiches, or extract. The general condition improved greatly and, as shown in the accompanying table of blood counts, the erythrocytes increased in numbers. The patient discharged himself on July 12th to attend to certain family matters.

On August 24th, 1928, he returned with great abdominal distension, causing much pain. The hydropneumothorax was still present, the heart was displaced 1½ in. to the left, the liver and spleen were unaltered, and there was marked tympanites and free fluid in the abdomen. The tympanites was intractable to enemas and stupes, but was reduced temporarily by pituitrin and eserine injections; 35 oz. of fluid were drawn off from the right side of the chest and 35 oz. from the abdomen. The fluid and tympanites, however, soon reaccumulated, and pericardial friction sounds appeared on Sept. 20th. A week later signs of pericardial effusion were present, and death occurred on Oct. 3rd, 1928.

Finding at Autopsy.

Post-mortem examination was done three hours after death.

The body was wasted. The right pleural sac contained a large quantity of serous fluid, the pleura was thickened, and the lung collapsed (weight 650 g.). The left pleura was covered by a "buttery" fibrinous exudate, causing several soft adhesions. The left lung was œdematous and contained healed tubercle at the apex (weight 850 g.). There was no thickening of the pulmonary vessels. The pericardium was thickened and contained an excess of fluid. The heart (weight 200 g.) was small and atrophied; the muscle soft, and "thrush breast" markings present on the endocardial surface. There was early atheroma involving the mitral valve. The aorta was smooth with remarkably little atheroma. The coronary arteries were patent and tortuous, not atheromatous and not markedly thickened.

The peritoneal cavity contained a large excess of serous fluid and the intestines were matted together by a fibrinous exudate, causing loculation. The spleen (weight 1450 g.) was greatly enlarged, and its capsule enormously thickened, being one inch thick at the lower pole. The Malpighian bodies, where visible, were much enlarged. The liver was enlarged (weight 1700 g.), its capsule was thickened, and on section its markings were very distinct. The ferrocyanide test was indefinite. The kidneys appeared normal, the capsule stripped easily, leaving a smooth surface. The right contained a white infarct; in one of the calyces of the left kidney there was a large quantity of gravel. The stomach was small and atrophied and embedded in the thickened splenic capsule.

The left femur was completely filled with red marrow except for two small areas in the condyles, where yellow marrow remained; the same intense marrow activity was seen in the ribs, vertebræ, and sternum. Sections showed active hæmopoiesis in the bone-marrow, and a few areas of hæmopoiesis in the spleen. The lung tissue, apart from some congestion, appeared normal; there was no thickening of the pulmonary arterioles. There were slight but definite deposits of hæmosiderin in the liver cells.

Discussion.

The association of gout and erythræmia has been previously noted.[23–25] and Waltersdörfer,[25] describing a case before the Hufeland Society in Berlin, considered the gout to be the causative condition. In one of Weber's[26] cases polycythæmia rubra commenced with frequently recurring attacks of gouty arthritis. It is possible that this association is related to the increased purine metabolism following over-activity of the myeloid tissues and the excessive blood destruction.

One may readily conceive that the flooding of the peripheral circulation with the red cells produced by the hyperplastic marrow calls for increased activity on the part of the hæmolytic mechanism of the body. Anæmia may thus result if hæmolysis becomes so excessive that over-compensation occurs. The increase in the size of the spleen noted in some of these cases certainly suggests increasing hæmolytic activity, and cannot be due entirely to the myeloid and erythroblastic metaplasia which takes place. Evidence of increased hæmolysis is found in the icteric tint of these patients, the positive indirect van den Bergh reaction of the blood, the increase of urobilin in the stools, and the deposits of hæmosiderin in the liver. In the first case described by Delhougne, Gotschlich, and Froboese there was very marked deposition of hæmosiderin in the tissues. There is an increase of red cell fragility, and the presence of hæmolysins in the blood is demonstrated by the more ready hæmolysis of normal red cells in dilutions of erythræmic blood serum as compared with normal serum.[14] This hæmolytic power of the serum is also seen in pernicious anæmia and *Streptococcus hæmolyticus* septicæmia.[27]

Experimentally, a condition strikingly similar to this anæmia found following polycythæmia has been induced by repeated blood transfusions in animals. Hess[28] and Itami[29] described extreme plethora in rabbits, which, in spite of continued transfusions and the absence of isolysins developed into a marked anæmia and bone-marrow aplasia. Robertson,[30] in a more thorough description of this type of anæmia, has shown the relationship of plethora and anæmia to myeloid activity, as indicated by the percentage of reticulated cells. He found that agglutinins developed coincidently with the anæmia. Kambe and Komiya[31] demonstrated quantitatively the presence of these agglutinins. Ottenberg and Thalhimer,[32] working with cats, found no isohæmolysins in the blood of the normal animal, but that they often appear in the blood of recipient cats after transfusion. With the development of hæmolysins a marked anæmia appeared from which they quickly recovered after the cessation of transfusions. Since Boycott and Douglas[33] could find no evidence of isohæmolysins after transfusions, they concluded that transfused red cells were not destroyed by direct hæmolysis. Krumbhaar and Chanutin,[34] watching the effects of repeated transfusions of blood on the blood-destroying and blood-forming apparatus of normal and splenectomised dogs and rabbits, found a decrease or absence of reticulocytes from the blood stream during plethora, and an increase during "plethoric anæmia" evidently due to depression and activation respectively of bone-marrow activity. Increased blood destruction and elimination also occurred as measured by urobilin excretion, which was greatly increased during the stage of polycythæmia, and still more so with the development of anæmia. Deposits of blood pigment chiefly in the form of hæmosiderin were found in enormous quantities in the spleen, liver, lymph nodes, and bone-marrow.

It is possible that the anæmia in the case described is, partly at least, the result of an exhaustion of the erythropoietic activity of the myeloid tissues; yet of the cases which have come to autopsy, five in number (Freund, 1; Minot and Buckman, 1; Delhougne, Gotschlich and Froboese, 2; Avery, 1), in two only was an aplastic marrow found (Freund, D. G, and F.); the others showed very active erythropoiesis. Both the cases with aplastic marrow were complicated by syphilis, and it is likely that the antisyphilitic measures affected the bone-marrow, for Frank[35] has shown that salvarsan can produce an aplastic anæmia.

Though excessive irradiation may lead to an anæmia, this is likely to be a temporary phase only, the result of destruction of erythropoietic tissue, but the hæmolytic function of the spleen is also impaired, so that the final result when the spleen has been irradiated will probably be worse than at the outset, as atrophy of that organ will ensue and, as after splenectomy, the cessation of hæmolysis by the spleen will result in an increase of red cells. When the long bones have been irradiated regeneration soon continues the original activity. In three of the cases described irradiation had been carried out before the appearance of anæmia, in two cases (Minot and Buckman, D. G, and F.), two years before the appearance of anæmia, and in one case (Avery) five years before. Minot and Buckman's other two cases were irradiated over the spleen with radium after the onset of anæmia, and both seemed to benefit (? depression of hæmolysis). It is interesting to note that Parkes Weber[26] has described a case of myeloid leukæmia in which X radiation of the spleen, though causing a drop in the leucocyte count from 856,000 to 60,965, resulted in a rise of the erythrocyte count from 2,016,000 to 6,000,000, indicating the effect of depression of both leucocytopoiesis and hæmolysis. It therefore appears that irradiation is not the ætiological factor in this transition of polycythæmia to anæmia.

Summary.

1. A case is described in which polycythæmia rubra vera of several years' standing passed into an anæmia resembling pernicious anæmia. Liver treatment resulted in a marked improvement in the blood picture, but the patient died of an intercurrent polyserositis. Marked hæmopoiesis was seen in the bone-marrow. 2. The association of gout with erythræmia is noted, and has been previously described. It has even been propounded as a possible ætiological factor. 3. Blood destruction is shown by the presence of blood pigments in the blood serum, by the increased excretion of urobilin, and by the deposits of hæmosiderin. It has been demonstrated that the serum of erythræmic patients exerts a hæmolytic action on normal red corpuscles. 4. Diminished erythropoiesis was the cause of the anæmia in two cases, for an aplastic bone-marrow was found at autopsy; but both these cases were syphilitic, and aplasia may have been the result of antisyphilitic measures. 5. Excessive irradiation of the spleen is unlikely to be the cause of the anæmia, and may, in fact, increase the polycythæmia by diminishing hæmolysis. 6. The anæmia is probably the result of excessive hæmolysis, the over-balancing of a compensating mechanism, though there may also be a slight reduction of erythropoiesis (as compared with the height of the polycythæmia, but yet greater than normal), as is seen in animal experiments.

My thanks are due to Dr. W. J. Adie, under whose care the patient attended hospital, and to Dr. A. R. Berrie who carried out the blood counts.

FURTHER OBSERVATIONS ON THE ÆTIOLOGY OF PSITTACOSIS.

By S. P. BEDSON, M.D., M.Sc. Durh.,
SENIOR FREEDOM RESEARCH FELLOW, LONDON HOSPITAL;

G. T. WESTERN, M.D. Camb.,
PHYSICIAN IN CHARGE OF THE INOCULATION DEPARTMENT OF THE HOSPITAL;

AND

S. LEVY SIMPSON, M.D. Camb., M.R.C.P. Lond.,
MEDICAL FIRST ASSISTANT AT THE HOSPITAL.

In a previous communication[1] we reported that a filtrable virus had been isolated from a parrot which had died from psittacosis, and which during life had been responsible for two cases of this disease in man. In view of our inability to obtain bacteriological or serological evidence of infection with *B. aertrycke* or any of its allies in a considerable number of cases of psittacosis both in man and parrots, it was suggested that this filtrable virus was the ætiological agent of the disease. Since the publication of that paper our work has been carried considerably further and, though the investigation is still far from complete, results have been obtained which we consider to be of sufficient interest to place on record.

Investigation of Diseased Parrots.

Twelve parrots have now been investigated, but of these six only had been responsible for human psittacosis. Only three of these six parrots have been examined for the presence of a filtrable virus, and in all three evidence of such a virus has been obtained. *In each case the filtrate of an organ suspension has* produced a fatal disease in budgerigars, and one of these strains has now been carried to the third generation in budgerigars, filtered material being employed throughout. The filters used have been Chamberland L1* candles, and the Seitz E.K. filter, and in every instance the efficiency of the filters in arresting the passage of bacteria has been controlled. Control budgerigars inoculated with unfiltered suspensions of either parrot or budgerigar organs which had been heated to 100° C. for 20 minutes, have remained well. In none of these six parrots has any member of the salmonella group been isolated. The remaining six parrots, which were sent to us because they were ill but which had not been responsible for disease in man, have been submitted to a thorough bacteriological examination. In five of these birds no member of the salmonella group has been found, but from the remaining one *B. aertrycke* has been isolated. This parrot is of particular interest, for the post-mortem picture which it presented was so different from what had been observed in the other parrots, including the three from which we have obtained a filtrable virus, that even the most uninstructed and casual observer could not have failed to note the difference. During life there was nothing in the appearance or the symptoms of this bird which distinguished it from those suffering from psittacosis; further, in this particular bird *B. aertrycke* was isolated from the heart blood, liver, spleen, pericardial fluid, and intestinal contents with the greatest ease.

We feel that this observation is additional evidence that *B. aertrycke* is not the ætiological agent of psittacosis.

Investigation of Human Psittacosis.

We have inoculated budgerigars with material from eight human cases and in every instance have produced disease in these birds. The material employed has consisted of citrated blood (equal parts of blood and 2 per cent. citrate in saline) in six cases, blood serum in one, and pleural exudate in one. This material has not been filtered but has been tested culturally and with the exception of one blood (Mrs. X., see Table), which contained a few *Staphylococcus albus*, has been shown to be sterile. Control birds have been inoculated with normal human blood collected in citrate. The results of these experiments are given in Table I.

TABLE I.

Budg.	Material inoculated.	Period in illness when collected.	Size in c.cm. and route of inoculation.	Result. (d = day).
17.	C. bl. (Mrs. Y.).	Day. 7th.	1·0 i.p.	Ill 7th d., killed v. ill. 11th d.
18.	C. bl. (Mrs. X.).	8th.	1·0 i.p.	Ill 7th d. Died 10th d.
19.*	C. bl. Normal.	—	1·0 i.p.	In good health 16th d.
33.	Pleural exudate (A. B.).		0·5 i.p.	V. ill, killed 8th d.
34.	Serum (C. D.).	10th.	0·3 i.p.	V. ill, killed 6th d.
37.	C. bl. (E. F.).	4th.	0·5 i.m. 0·5 i.p.	V. ill. Still under obs. 8th d.
38.	"	"	"	Moribund 6th d., killed.
43.	C. bl. (G. H.).	"	0·5 i.m. 0·5 i.p.	V. ill. Still under obs. 5th d.
44.	C. bl. (I. J.)	"	0·5 i.m. 0·5 i.p.	Died 3rd d.
45.	C. bl. (Mrs. Z.).	11th.	0·5 i.m. 0·5 i.p.	Died 4th d.
47.*	C. bl. Normal.	—	0·5 i.m. 0·5 i.p.	In good health 6th d.

* Control. C. bl. = Citrated blood. i.p. = Intraperitoneal. i.m. = Intramuscular. obs. = Observation.

From budgerigars 18 and 34 we have been able to pass the disease with filtrates of a suspension of liver and intestine, thus carrying the investigation of these two human strains a stage further. The results of these experiments are given in Table II.

TABLE II.

Budg.	Material inoculated.	Size in c.cm. and route of inoculation.	Result.
39.	Filtrate of 10 per cent. liver suspension from budg. 34.	0·5 i.m.	Died 4th day.
40.		0·5 i.m.	Very ill 5th day.
41.	Filtrate of 10 per cent. liver and intestine suspension from budg. 18.	0·5 i.m.	Killed, moribund 3rd day.
42.		0·5 i.m.	Died 4th day.
46.*	Unfiltered suspension Budg. 34. Heated at 100° C. for 20 minutes.	0·5 i.m.	In good health 6th day.

* *Control.*

Epidemiological Data of Cases Under Investigation.

It is not proposed to enter into this question in any detail, for this will be dealt with fully at a later date by the clinicians responsible for the cases. In view, however, of the evidence which we have obtained of

the presence of a filtrable virus in human cases of psittacosis, it might not be out of place to give some of the facts, particularly in reference to the two cases Mrs. X. and C. D. The former was one of five cases occurring in a house in Walworth-road, London. The parrot was brought on Dec. 11th, 1929, fell ill shortly after, and died on Dec. 22nd; it was destroyed. The patient denied any direct contact with the parrot, though she had been in the same room with it. She had, however, nursed another member of this group whose illness commenced on Dec. 21st, 1929. The patient, Mrs. X., fell ill on Jan. 12th, 1930, and was seen on Jan. 19th, when she was admitted to the London Hospital; she is now recovering. The specimen of blood was taken on this day—the 7th day of illness—when the disease was almost fully developed. C. D., aged 58, was one of four cases of psittacosis which developed in a house in Warwick. There were two parrots associated with this case, both of which died. One was dug up after burial, and sent to us for examination on Jan. 21st, and we have been able to kill budgerigars with the filtrate of a suspension of its organs. The patient was taken ill on Jan. 7th, 1930, and died in the Birmingham General Hospital on Jan. 18th. The blood from which we obtained the serum for inoculation of budgerigars was collected on Jan. 17th. We are indebted to Prof. G. Haswell Wilson and Dr. A. P. Thomson for material from this and one other case. In the latter of these two cases (C. D.) the disease appears to have been contracted from the parrot directly, but in the former (Mrs. X.) the evidence strongly suggests infection by contact with a human case. This is made all the more probable by the fact that the patient used a handkerchief in common with her sick relative whom she was nursing. There is one other case which calls for some mention, that of Mrs. Z., because it demonstrates the fact that parrot carriers exist, which, although in apparently good health, can communicate the disease to man. The parrot in this case was a grey one which was caught in Africa (Gold Coast). It was ill at the time, and was nursed by its captor and recovered after an illness lasting three months. Three months after recovery it was brought to this country and given to Mrs. Z., who has had it in her possession for eight months. Apart from transient attacks of diarrhœa it has been in good health. On Jan. 9th Mrs. Z. was bitten on the tongue by this bird, and she fell ill on Jan. 19th. She was seen by one of us on Jan. 30th, when the specimen of blood was taken with which budgerigars were infected (Table I.). This parrot is in our possession, and will be investigated.

Nature of the Virus.

At this stage of our investigation we are not in a position to say much about the nature of the virus which we have isolated. It appears to filter readily and to have a fair degree of resistance to glycerol. The strain isolated from the first parrot has been inoculated in hens (2), pigeons (2), and guinea-pigs (2). The guinea-pigs and pigeons have remained in good health, but the two hens sickened some nine days after inoculation, and are still very ill 20 days after infection. The possible relationship between this virus and the virus of fowl plague is still under investigation. Although we have no proof as yet that the parrot and human strains of virus we have isolated are the same, there can be little doubt that they are; the final proof of this will be a matter of future study.

In conclusion, we would again wish to express our indebtedness to our colleagues of the London Hospital and other doctors who have provided us with material for this investigation. In particular we especially wish to thank Dr. Robert Hutchison, Dr. R. A. Rowlands, and Dr. Donald Hunter of the London Hospital, and also Dr. W. J. C. Fenton of Barking, through whose energetic coöperation we have been able to investigate an outbreak of four cases in a family in Barking. We are grateful to the Yarrow Fund for a grant towards the expenses of this research.

Clinical and Laboratory Notes.

A NOTE ON
REMEDIAL EXERCISES IN THE TREATMENT OF PULMONARY DISEASES.

By A. H. Douthwaite, M.D., F.R.C.P. Lond.,
ASSISTANT PHYSICIAN AND PHYSICIAN IN CHARGE OF THE MASSAGE DEPARTMENT, GUY'S HOSPITAL;
AND
H. S. Angove,
SISTER IN CHARGE OF MASSAGE DEPARTMENT.

The high incidence of pulmonary complications in recent epidemics of influenza has prompted this brief account of the methods and results of physical treatment as applied to the common diseases of the lungs and pleura. The advances made in the surgery of the chest, lately reviewed by R. A. Young[1] in his Lumleian lectures, make a wider knowledge of the importance of after-treatment essential. For purposes of description, the types of case suitable for physical therapy may be divided into three groups:—

1. Those in which the expiratory function is in need of assistance—e.g., emphysema, asthma, bronchiectasis.
2. Those in which aid to inspiration is desirable—e.g., empyema, pulmonary collapse.
3. Those in which both inspiration and expiration are interfered with—e.g., chronic bronchitis, pneumonias with delayed resolution.

In certain pulmonary diseases, particularly those of chronic nature, the muscles of the chest wall assume a new postural length and tone, adapted to the changed contour of the thorax. This alteration tends to establish itself as a permanent condition and inevitably leads to rigidity of the parietes and seriously interferes with curative efforts. It will be seen, then, that a mobile thorax must be attained before passing on to those exercises and manipulations whose object it is to affect the deeper structures. Furthermore, it is usually desirable to apply massage to the limbs in order to aid the circulation and prepare the body for the introduction of active work.

All the respiratory exercises produce a beneficial effect on the condition of the thoracic joints and muscles, yet certain schemes are directed primarily toward this end. These consist of encouragement of the movements of flexion, extension, and rotation of the spine, at first carried out singly and later in combination.

Treatment of Thoracic Contents.

1. *Chest Clapping.*—A series of short quick strokes on the chest wall has been found to assist in loosening tenacious mucus, probably indirectly by the sudden multiple expulsions of small volumes of entrapped air.

2. *Chest Shaking* is carried out during expiration only, the hands being placed on the chest and given a rapid in-and-out shaking movement. An effective assistance to expiration is thus obtained.

3. *Vibration* is merely a modification of 2, in that the movements are finer and less vigorous.

4. *Controlled and Localised Breathing.*—Patients are first taught to produce the thoracic or abdominal type of respiration at will. When this can be rendered efficiently, they pass on, if indicated, to exercises in which a part of the chest is fixed in order to promote more efficient expansion in the diseased area of lung. The patient's arm is placed firmly against the normal side, the forearm passing across the abdomen, and the hand grasping the iliac crest of the opposite side. This attitude limits the movement of the diaphragm on the healthy side, and the gymnast completes the fixation by placing her hands on the

---

[1] The Lancet, 1929, i., 805.

front and back of the chest. Respiration is then carried out at first quietly, then with deep inspiration, the effect of which can be fortified by holding the breath; at this stage the arms may be extended above the head. The latter exercise is of special value in aiding expansion of collapsed lung, and more effective than the old method of blowing water from bottle to bottle, an exercise which is apt to produce a strained attitude with fixation of the thorax. Yet more pronounced effects may be obtained by changing the position of the chest. Thus bending laterally will open out the intercostal spaces on the opposite side and so aid expansion. This can be accentuated by fully extending the arm on the side of the convexity.

5. *Alteration of Posture.*—If it is desired to empty pus-containing cavities, the chest is tilted downwards, the legs lying across the couch, the hands resting on the floor. This position must, however, be carefully supervised, and not undertaken without a careful review of the general condition. It may be advantageously combined with shaking and vibration.

Precautions during Treatment.

In diseases of the lungs in which there is no open wound, or in which a suspicion of tuberculosis is entertained, pulse-rate and temperature are used as guides to the extent of each individual treatment. If there is no independent disease of the myocardium, it is safe to raise the pulse-rate 20 to 30 beats in older people, and 30 to 40 in the young, at each treatment, provided that it returns to normal within three minutes after cessation of exercise. Work of this degree produces sufficient acceleration of respiration to attain the desired result. If, on the other hand, the pulse-rate shows from day to day a persistent rise, exercise must be stopped or reduced. If the temperature is above normal in the morning, treatment for that day should be omitted; if it persists, treatment should cease. In pleural effusion persistent pyrexia is a contra-indication to exercise. Should there be an open wound, as in empyema, pyrexia often denotes faulty drainage. It may then subside if the movements of the chest be increased in extent. If after two or three days the fever persists, however, exercises must cease pending further surgical treatment.

General Scheme of Treatment.

A general scheme of treatment would include: (1) active movements of arm or leg to increase respiratory excursions; (2) bilateral free breathing; (3) active movements, arm or leg plus postural training; (4) localised breathing (controlled); (5) movements of the trunk; (6) localised breathing (controlled); (7) repeat (3); (8) repeat (6); (9) repeat (3); (10) bilateral free breathing.

Two sets of active movements only need be used, and in the early stages movements for the trunk may be omitted. The training of posture from the very beginning is important; the arm-chair bed and the head pushed forward on the chest are both to be avoided from the first. The scheme is made more vigorous by (*a*) changing posture, from lying to sitting and finally standing, (*b*) increasing the number of times each exercise is performed. Each movement usually begins six times and is increased one, two, or three times a day, until it produces the desired effect; (*c*) adding a resistance to the movement such as lifting a pound weight in each hand; (*d*) increasing the rate and duration over a given time for each exercise.

Differential Treatment of the Three Groups.

Group I.—A. F. Hurst,[2] writing on the value of remedial exercises in asthma and emphysema, stresses the importance of recognising and correcting the postural errors which develop and tend to persist in these diseases.

With this aim in view, treatment is initiated with exercises to restore to normal the position of the shoulder girdles, thoracic walls, and abdominal musculature, and at the same time to increase the range of mobility of the spine and costal articulations. Breathing exercises are taught next, particularly with a view to encouraging expiration. Each consists of three and a half respiratory cycles, and commences with forced expiration. There are, therefore, four deliberate expiratory to three inspiratory movements. Air is drawn in through the nose and expired through the mouth, the tongue and teeth being in the position for sounding the letter S. The end of each voluntary expiration is assisted further by the patient, whose efforts are reinforced by the masseuse, applying "thoracic shaking" to different areas, the hands being placed first on the antero-lateral aspect of the chest, then in the mid-axillary line, the apices, and finally the posterior wall of the thorax. In the last position the patient bends backwards over the assisting hands during expiration in order to promote correction of the acquired kyphosis.

These respiratory gymnastics should be carried out sometimes with the thoracic, sometimes with the abdominal, and at times with the combined type of respiration, all of which have to be explained and taught to the patient if success is to be achieved. It will be observed that the object of the above treatment, both in asthma and in emphysema, is to reduce the bulk of the lungs and increase the power of the expiratory muscles. In the former disease, much of the apparent emphysema is due to simple over-distension, which is amenable to physical treatment. In the latter affliction, although the emphysematous areas must remain as such, yet large areas of the lung are in a pre-emphysematous stage—i.e., over-distension without atrophy of lung tissue, and if this be corrected, the destructive process will be materially retarded. Furthermore, improvement in the respiratory excursions in both cases must act beneficially on the pulmonary circulation and consequently upon the heart muscle and systemic system.

The same treatment is given in cases of bronchiectasis, but, in addition, the patient is tilted trunk downwards, and vigorous chest shaking performed during expiration. Large quantities of foul sputum are thus evacuated with frequently dramatic improvement in the general condition.

Group II.—Empyema forms the most important member of this group, and its management alone will *therefore be considered in detail.* There are few conditions in which early attention to physical treatment is of such paramount importance. For several years it has been our practice to start exercises within 24 hours of the operation in order to (1) promote expansion of the lung and, therefore, adequate and complete drainage of the empyema cavity; (2) prevent scoliosis. That absorption of toxins is accelerated by early exercises is not borne out by our experience, in fact, the reverse seems to be the case. On the other hand, secondary operations necessitated by pocketing of pus, or persistence of an infected sinus, become progressively rarer the earlier the exercises are undertaken. When instituted almost immediately after operation, healing takes place in two or three weeks with almost perfect expansion. During the first 48 hours treatment the dressings remain undisturbed, and no active limb work is given. The pulse is taken before and after exercise. Some degree of pyrexia is, of course, present during the first few days, but forms no contra-indication to treatment. After the first two days the tube is removed and the wound covered with a dressing before the exercises are carried out. Thereafter the tube is replaced and the wound dressed afresh.

The first scheme consists of: (1) deep breathing, insistent instructions being given to encourage the taking of deeper breaths; (2) readjustment of position—e.g., a pillow to throw the chest slightly forward, thus bringing the neck into line with the trunk; (3) kneading to the arms; (4) deep breathing. This is repeated the next day, and from the end of the second treatment active work is added, care being taken to restrict movement on the normal side.

The following progression of exercise is made. *Arm:* Double arm bending and stretching—i.e., flexing and extending the arms from the side to above the head. Begin six times and progress daily, until the movement is performed 36 times a minute for three minutes. The patient may hold a weight of one or two pounds in the hands if more exercise is required. *Leg:* Alternate, and later double leg bending and stretching. Beginning six times and increasing daily as for the arm. *Trunk:* No movements are given during the first week of exercise. Later, trunk movements are introduced.

---

[2] Guy's Hospital Reports, January, 1927.

After each set of active movements localised breathing is carried out. This must be (*a*) with the normal chest fixed; (*b*) with the arm of the affected side gradually raised above the head; (*c*) with the trunk bent to the opposite side. These breathing exercises are usually taken from the following position. Half lying: the usual position for an empyema to be nursed. Lying, and lying with the trunk bent to the opposite side. Sitting, and sitting with lateral bending. Standing, similarly combined with bending to the side. Each breath is held for a moment at the end of full inspiration. Shaking and clapping should be avoided whilst there is an open wound. When the patient is allowed to get up, walking, running, and skipping are gradually introduced as immediate precursors of the breathing exercises.

Pyrexia does not necessitate discontinuing treatment, provided that the wound remain open, unless the raised temperature persists for longer than three days. A persistent rise in pulse-rate frequently denotes that too much exercise is being given.

Group III.—The danger of fibrosis of the lung and bronchiectasis as sequelæ to broncho-pneumonia has long been recognised, and a large number of influenzal pneumonias, although of lobar type, present persistent signs of massive consolidation for weeks after the pyrexia has subsided. In others the greater part of the affected lobes pass through the normal resolution, leaving a basal patch of dullness, bronchial breathing, and coarse râles which fail to clear up in spite of complete subsidence of constitutional disturbance. The value of remedial exercises for these conditions lies largely in the induced increased respiratory excursions which act as a stimulus to the pulmonary circulation in the affected areas. The increased blood flow enhances the process of cleansing of the site of the inflammatory products, thus effectively forestalling the changes of organisation. In influenzal pneumonia it is well to delay treatment until the temperature has been normal for a week. In broncho-pneumonia a low but persistent grade of pyrexia may follow the acute stage. If this be the case, exercises can be cautiously instituted, and not infrequently result in a fall of temperature to normal.

The actual procedure is the same as that outlined in the case of empyema, and should continue until resolution is complete. Daily instruction must be given until the patient is well grounded in the exercises, which should be carried out thrice daily. After this, weekly supervision is probably all that will be required. Chest shaking, clapping, and vibration are also indicated in cases of slowly resolving broncho-pneumonia.

Failure to achieve success when dealing with this group is unusual, and then referable to undue delay between the termination of the acute illness and the initiation of the physical therapy which we have described.

A CASE OF
CARDIAC HYPERTROPHY IN AN INFANT.

BY J. J. SAVAGE, M.B. OXF., F.R.C.S. ENG.,
RESIDENT MEDICAL OFFICER, NORTH DEVON INFIRMARY, BARNSTAPLE.

A MALE child, aged five weeks, was brought recently to the North Devon Infirmary, Barnstaple, in a state of great weakness and with marked cyanosis. The lips were a bright purple, the face had a distinct bluish tinge, the fingers were clubbed, and the hands were dusky.

The child had been breast-fed, but was so feeble that it had never been known to cry; its only efforts in that direction were confined to a few abortive gasps, accompanied by a distortion of mouth and facial muscles. It was fairly well nourished, and weighed on admission 7 lb. 8 oz., as contrasted with 7 lb., its weight at birth.

On examination the most marked manifestation was the terrific effort made in inspiration. The whole chest heaved and seemed to lift itself bodily from a globular abdomen. The sides of the ribs were indrawn, as also the axillary spaces, and the intercostal muscles were definitely retracted into troughs and hollows along the chest wall—a condition which, except for the absence of stertor, was highly suggestive of diphtheritic tracheitis.

On percussion a pronounced dullness was remarked over the cardiac area and extending well to the right of the sternum, but no thrill nor præcordial pulsation could be felt, nor was any murmur heard. Bearing in mind the condition of pulmonary atelectasis, I was surprised to note that the lungs posteriorly were clear and resonant to percussion, and that the breath sounds were characteristic of normal infantile vesicular breathing.

No radiogram was taken, and the child died suddenly 24 hours after admission.

Post-mortem examination.—On removal of the chest wall the heart presented an unique spectacle. It occupied four-fifths of the whole thoracic cavity. The lungs were nowhere to be seen anteriorly, and the cardiac mass suggested nothing so much as an overgrown liver that had been thrust bodily upwards through its diaphragmatic roof. The weight of the heart was 4½ oz., and its size was 2¼ in. by 2½ in. It resembled a huge duck's egg, being five or six times the size of the infant's fist, which is generally considered a fairly reliable index of normal cardiac measurement.

On removing the pericardium the hypertrophy of the right side was at once brought to view—the walls of the right ventricle being twice as massive as those of the left; indeed, in their upper part they were over half an inch thick. The pulmonary artery was widely opened, having a calibre in cross section of an ordinary lead pencil. There was no trace of a permanent ductus arteriosus. The ventricles were healthy, as also was the interventricular septum, and the only lesion discovered was a small obliquely vertical aperture, 5 mm. by 2 mm., in the fore part of the membranous diaphragm of the fossa ovalis. That so small an aperture could be responsible for such cardiac hypertrophy, and so pronounced a cyanosis, appears remarkable, but the conclusion seems inevitable.

During the child's short stay in hospital its condition was only partially relieved by oxygen. The general respiratory enfeeblement and the absence of crying completed the picture of a child being slowly asphyxiated by tardy and imperfect oxygenation due to a primitive hiatal defect in the pulmonary system. The enforced limitation of a normal respiratory excursion was brought about by the presence of a tumour-like mass—the self-destroying cardiac hypertrophy—Nature's too prolific response to the call of a heavily burdened infantile heart.

I am indebted to Dr. S. R. Gibbs, hon. physician to the hospital, for permission to make these notes.

A NOTE ON THE
RELATIVE SEPTICITY OF THE DUMMY TEAT AND THE THUMB.

BY E. A. BARTON, M.R.C.S. ENG.,
MEDICAL OFFICER TO THE CHILD WELFARE DEPARTMENT, UNIVERSITY COLLEGE HOSPITAL, LONDON.

THE first instinct in life, and the first desire of an infant is to suck something, preferably the maternal nipple; but when this pleasure is denied, consolation is obtained from the nearest available substitute. Very young infants do not suck their thumb; this habit is acquired toward the middle of the first year as soon as the way to the mouth has been discovered by the hand; and the fact that a dummy teat has never been offered to the infant does not prevent the child from thumb-sucking later. The ideal infant would not attempt to suck either the dummy or the thumb, but however one may advise, there are mothers who will give a dummy for the sake of peace especially amongst the very poor where a whole family occupy a single room, and are compelled by circumstances or a tired husband to quiet a noisy infant. Nor can one seriously blame them, for the use of the dummy is far less baneful than to allow the child to suck its thumb. The dummy made of smooth composite rubber and not perforated—as is the bottle teat—allows no air to be sucked through it, and I have yet to find an infant seriously upset by anything that could honestly be ascribed to the dummy. Of course, if the mother moistens the dummy with her mouth before inserting it into that of the child, therein lies a certain risk of infection from anything from which the mother may suffer; but otherwise there can be but little more harm in sucking a smooth dummy than that attached to the bottle from which he sucks for a considerable time daily. I am sure that there is a tendency to magnify the evils of a dummy, though the evils of thumb-sucking can hardly be exaggerated.

The thumb has a comparatively rough surface, is rarely cleansed, and is used prehensilely with every grasp of the hand, so that the surface becomes excessively foul. I have lately had the great advantage of the assistance of Dr. F. H. Teale and his staff in making some observations on the comparative septicity of the dummy and the thumb, and in ascertaining approximately which of the two is the greater source of possible infection.

Technique.

A sterile swab was dipped into a tube of 10 c.cm. of culture medium, and wiped three times against the side of the tube to remove excess of medium. The dummy, or the thumb, was then wiped six times in different directions in its long axis. The swab was then immersed in the culture medium and stirred for five seconds. Graded quantities of this emulsion were immediately plated out and after 24 hours' incubation the colonies were counted, averaged, and the results expressed as numbers of colonies per c.cm.

Results.

Case.	*Dummies.* Colonies.	*Thumbs.* Colonies.	Case.	*Dummies.* Colonies.	*Thumbs.* Colonies.
1	26	300	7	420	5000
2	115	Innum.	8	112	322
3	1560	1240	9	1920	446
4	716	Innum.	10	900	580
5	1000	3500			
6	166	Innum.		6935	11,388

Innum. = Innumerable, and signifies colonies of over 20,000 in number.

If we take "innumerable" at 20,000, the comparative figures are for the dummy 6935 colonies, whereas the number of colonies for the thumb amount to 71,388 or over ten times that of the dummy. The thumb therefore is ten times more septic than the dummy.

Remarks.

Apart from the effect of constantly sucking the foul thumb, there is another side which demands consideration. The thumb is a hard body, and if frequently in the mouth tends to pull forward the growing pre-maxilla together with their incisor teeth, so that the upper incisors project forward often beyond the upper lip, giving the "dents des Anglaises" appearance which the French so love to caricature. When the child has cut its second dentition the dentist then reaps his harvest of extractions and plates with wired tensions to press into place the prominent incisors. Another result of the thumb-sucking lies in the fact that the thumb having a joint, the ball of the thumb is flexed in the mouth and the palate is thus pressed up into a high arch at the expense of the nasal floor, thus lessening the lumen available for breathing through the nasal passages, with consequent congestion and all the associated evil results.

BRISTOL EYE HOSPITAL.—Last year this hospital treated 550 in-patients and 13,683 out-patients, and it is no longer possible to cope with the demands upon accommodation. A new building, to cost £50,000, is therefore to be erected, containing a children's ward, two wards for infectious cases, wards for paying patients, more accommodation for the staff, and a larger out-patients' department.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

A MEETING of this Section on Feb. 5th, with Sir HOLBURT WARING, the President, in the chair, was devoted to a discussion on

INTRATHORACIC TUMOURS.

Mr. A. TUDOR EDWARDS referred to the question whether the recent increase in the reported cases of primary malignant disease in the thorax was due to a real increase in incidence or to better methods of recognition. A similar increase in benign growths in this region suggested that the second explanation was the right one. Tumours of the thorax were divisible into mediastinal, pulmonary, pleural, according to their origin. Mediastinal tumours comprised benign tumours, such as goitres, dermoids, and teratomata and also aneurysms—a variety responsible for a good deal of difficulty in diagnosis. The primary malignant tumours were sarcoma, carcinoma of the thymus, and lymphadenoma. Secondary carcinoma in mediastinal glands arose from carcinoma of the bronchus, lung, or pleura, and also from primary carcinoma of the breast. Of the benign mediastinal tumours, intrathoracic goitres tended to remain localised in the superior mediastinum, and so behaved like benign growths in that region. Dermoids and teratomata, on the other hand, enlarged laterally. The chief early symptom of goitre was dyspnœa, but enlargement of the tumour results in venous obstruction, as shown by cyanosis of the skin of head and neck. Pressure on nerves seemed to be rare. The physical signs of these goitres, apart from toxic manifestations, were an area of dullness on percussion over the sternum and enlargement of veins in the same area. X rays showed a well-defined opacity in the upper substernal area; oblique views showed the tumour to be situated anteriorly. It might not be possible to diagnose this from dermoid. He did not think that mediastinal dermoids and teratomata often caused symptoms because of their position; but when they extended outwards there might be symptoms due to irritation or there might be rupture into a bronchus, the former being manifest by non-productive cough. When infection took place the signs were those of pulmonary abscess. In some cases pressure of the tumour on the lower lobe caused bronchiectasis. Unless infection supervened X rays clearly outlined the tumour, and when bone or teeth were present they gave a denser shadow. Induction of artificial pneumothorax would often make a distinction possible from intrapleural tumours.

Intrathoracic goitres, said Mr. Edwards, should be removed as soon as respiration was embarrassed; for the larger tumours it was necessary to split the sternum in the mid-line down to the third interspace. Dermoids and teratomata, when localised to the mediastimun, could be approached by the same route, but he preferred exposure through the pleura. In a general way it could be said that the large tumours should be exposed by a posterior incision, the smaller ones by the anterior route. After removal of the tumour the chest was made air-tight by approximating the muscle layers; he had not found that percostal or pericostal sutures were needed. He had operated upon seven cases of true intrathoracic goitre, and three required division of the sternum. Shortness of breath was a complaint in all, and two had been treated as asthma for three and four years. One post-operative death occurred among the seven; this patient had toxic goitre, and the thymus was found to be enlarged. There was also one death among seven cases of operation for teratomata or dermoids, the tumour in this case being of the size of a fœtal head. Mr. Edwards had also operated upon one cyst which contained 1½ pints of fluid, and the patient recovered and was still well four years later. With malignant mediastinal tumours operation was rarely possible, and more rarely still was there freedom from recurrence for any considerable time. Recurrent sarcomata seemed to be insensitive to X rays in treatment.

Benign pulmonary tumours were very rare. The most common cysts in the lung were hydatid, and might be single or multiple. They gave rise to cough and expectoration, and sometimes—when near the lung surface—to pain. Of malignant growths of the pulmonary region primary carcinoma might arise in the bronchi or in the alveoli, the former being the more common; it usually arose towards the hilum. Sarcoma here was much rarer than carcinoma. The types of sarcoma were the spindle-celled and the peribronchial infiltrating forms. In bronchial carcinoma dyspnœa seemed to be the earliest and outstanding symptom, and hæmoptysis might be the first event; in many cases the fever suggested influenza. The physical signs, in most, were those of atelectasis of the lobe which communicated with the affected bronchus. Lipiodol might confirm the diagnosis, for it showed an irregular blocking of the bronchus involved. Bronchoscopy would also reveal the condition. When secondary glands were present in the neck they should be removed under local anæsthesia and histologically examined. All types of malignant disease in the lung might have pleural effusion as a late sequel.

Only rarely, said Mr. Edwards, did bronchial carcinoma allow of radical operative removal—largely because of the early involvement of mediastinal glands. He had not yet seen even improvement in such cases as a result of deep X ray therapy, and various doses of radium as a surface application had, in his hands, been disappointing. Better effects, however, followed the use of radon seeds. These should be used only after full exposure of the tumour. Central carcinoma and endothelioma were much more favourable for operation. In secondary malignant deposits in the lung no form of treatment seemed to be of value, but partial pneumectomy was carried out in one case of secondary myeloma, the primary disease having been in the fibula, and the patient was still well two and a half years later. Most tumours characterised as pleural probably arose in adjacent structures and developed inwards. Benign tumours here should be removed surgically as soon as diagnosed if the general state permitted; otherwise life would be ended owing to pressure on important structures in the course of growth. The malignant tumours found in connexion with the pleura were endothelioma and sarcoma, and these caused localised thoracic pain, with pleural effusion, serous first and hæmorrhagic later. The localised type could be removed if diagnosed before secondary deposits were evident. Radium should be applied in sarcomatosis.

Discussion.

Mr. W. H. C. **ROMANIS** said that in some cases a large mass of thyroid tissue down in the chest had no visible connexion with whatever thyroid tissue might be present in the neck. When a rounded shadow appeared in the radiogram below the sternal notch this condition should be suspected. These retro-sternal goitres might be easy to remove or very difficult. He had only once found it necessary to split the sternum; sometimes they could be pulled out. Dermoids gave rise to a variety of manifestations, but pressure on important structures was not common with them, though in one case he had seen gross interference with the action of the heart. The best approach for removal was from the side, making a large incision between two ribs. Hydatids were so rare in this country that no surgeon or physician saw many of them. With regard to malignant disease of lung, the percentage of operable growths encountered by any surgeon was at present very small. The only means of making the proportion larger seemed to be early exploration of all doubtful cases. Radium treatment for these cases was at present in its infancy. He was not altogether a radium enthusiast, but he had tried radon seeds in some cases of growth of the lung, and they seemed to benefit some growths there, just as they benefited some growths of breast and tongue. He had one case at present which was a surgical failure but a radium success, and he thought there were likely to be a fair number of successes with radon seeds in pulmonary growths. Before exploratory thoracotomy and before removing most of these tumours it was essential to produce artificial pneumothorax. This should be done a day or two earlier.

Dr. L. S. T. **BURRELL** said that most of his patients who proved to have tumour of the chest came with the complaint of dyspnœa and were found to have pleural effusion; this was especially true of tumours of the pleura. The second great group of symptoms were those of pressure on a bronchus, the onset of which might be quite sudden. More than one of these cases had been diagnosed as pneumonia. Another initial symptom was hæmoptysis. Often he heard the remark "I don't think he can have malignant disease, for he has very few constitutional symptoms, and looks so well." But this was just the reason for suspecting malignancy. In most cases radiography would show a tumour, but more commonly it would show pulmonary collapse which it had caused. When effusion developed in cases of tumour it was, as a rule, blood-stained. A more frequent sign was an excess of endothelial cells. He regarded the use of lipiodol for diagnosis as very important. He agreed with Mr. Romanis on the induction of preliminary artificial pneumothorax; this enabled a thoracoscope to be used with the idea of seeing the tumour. Some cases which were thought to be lymphosarcoma of lung were in reality carcinoma, starting usually in a bronchus. Metastases were found in the liver in 40 per cent., the bones in 12 per cent., and the spleen in 10 per cent. In his view, there was only one treatment for the growths under discussion—namely, surgical operation. In every case he had seen which was treated by radium and deep X rays there had been recurrence. Radium seemed to be useless in intra-thoracic growth. He described five recent cases of his own.

Dr. F. G. **CHANDLER** showed and described a number of radiograms of cases of malignant thoracic tumour which had come under his care. Paralysis of the phrenic nerve, or of the recurrent laryngeal, must always be regarded as suggestive of growth; the suspicion was helped by the presence of secondary glands. An axiom he submitted was that it was better, in a doubtful case, to operate on a case of hopeless growth than neglect a case of abscess. Nor should it be forgotten that a mass evident to X rays might be gummatous. At present no form of treatment for these cases held any assured promise. Of 120 cases of primary malignant intrathoracic tumour, half of them treated by X rays and half by radium, only four were now alive.

Mr. W. A. **WHITE** said the commonest malignant growths of the chest were carcinomata, and many of them were inoperable. The commonest accompaniment was a dry unproductive cough, associated sometimes with severe convulsions and cyanosis. For the application of radium he used a small trocar and cannula of his own devising whereby he applied a radon seed fixed by paraffin wax to a stilette. On connexion with an electric current the wax was melted; the heat coagulated the tissues, the stilette was withdrawn, and the radon remained in situ. He showed a patient, well and strong, from whom he had removed a carcinoma which was growing into the mediastinum.

Mr. **JAMES MAXWELL** gave the results of the examination of 184 cases of primary bronchial carcinoma collected at St. Bartholomew's Hospital and the Royal Chest Hospital. He classified them according to site and method of spread. Six per cent. started in the roots of the lung and the surrounding bronchus alone; that type was not prone to cause early metastasis, and some success attended treatment. In 20 per cent. the growth infiltrated a lobe of the lung alone, and this was fairly easily amenable to radium or X rays. *In 25 per cent.* the mediastinum was infiltrated, not the lung. The bronchus and pericardium were early involved, and implication of aorta and important structures followed. It was always outside the scope of surgery, though it might be treatable with radium. In the fourth type both lung and mediastinum were infiltrated, and these were most difficult to treat. This was the most numerous type. It must be remembered that many people with malignant disease of the thorax also had tubercle bacilli in their sputum.

Mr. J. E. H. Roberts agreed with those who had a poor opinion of the result of deep X ray treatment of these carcinomatous tumours; he had not seen permanent benefit from it. Still its use would probably continue, for it was difficult to see the likelihood of cases being brought to the surgeon at an earlier stage. He had, however, seen several cases in which primary sarcoma had disappeared after the insertion of radium, and though patients died some two years later from metastases elsewhere, the primary growth, to the date of the death, had not recurred. It was very important to gain all possible information about the behaviour of the tissues of the lung in the presence of irradiation from X rays and radium.

SECTION OF OTOLOGY.

At a meeting of this Section held on Feb. 8th the chair was taken by Mr. W. M. Mollison, the President, and Prof. Heinrich Neumann, of Vienna, opened a discussion on

Brain Abscess.

He first commented on the astonishing fact that Macewen's statistics of 50 years ago were better than even the best figures recorded since. Macewen had selected his material, but even with selected cases Prof. Neumann could only get 47 per cent. of good results. Possibly Macewen's success had been partly due to his custom of postponing operation until protective adhesions had been stimulated in the dura by 20 per cent. carbolic acid, and to the fact that he had opened cerebellar abscesses without waiting for the characteristic symptoms which had been described by more recent workers.

(Prof. Neumann then showed and described a very large number of slides and specimens from his practice).

The shape of the abscess did not appear to be influenced by the presence or absence of a capsule, or by its origin from acute or chronic otitis. The *direction of growth and the position probably depended* upon the blood-vessels and the structure of the nerve-fibres. In spite of the uniformity of the pathological and anatomical picture, the clinical manifestations varied considerably, and seemed to be much influenced by the situation of the abscess. It was remarkable that abscesses were quite often diagnosed and sought by puncture, and yet no pus was found. Whether this was due to a thick capsule or to the consistency of the contents was not known, but puncture more often gave a negative result in cases of abscess following acute otitis than in those following chronic otitis. Failure to find pus in cerebellar abscesses was explained by the fact that the abscess cavity was flat or slit-shaped, so that the needle could easily miss it or pass right through it without yielding pus. The characteristic focal symptoms of both cerebral and cerebellar abscess appeared relatively late, and it was therefore wise to perform exploratory puncture as soon as the general state roused any suspicion of abscess. Despite the rarity of cerebellar abscess and the fact that its general symptoms could be produced by other conditions, it had been found worth while to pay great attention to the general symptoms, such as repeated vomiting, dizziness, and constant occipital headache. For the production of focal symptoms decomposition in the abscess as well as changes around it were important. Cerebellar abscess affected the white matter very late, and tended first to spread between the grey and the white matter. Specific symptoms only appeared when fibre-systems were encroached upon. Some patients might have been saved if they had been diagnosed and operated upon before these focal symptoms appeared. Hitherto, however, the dangers of puncture, especially of the posterior fossa, had discouraged workers from exploring in the stage of general symptoms. On the whole it was best not to incise the dura before puncture, on account of the risk of prolapse and of alteration in the circulation and tension of the cerebrospinal fluid.

Treatment must vary with every case; each abscess needed its own special method of operation. No kind of drainage was of any use for deep abscesses covered with a thick layer of encephalitic brain; only removal and tamponing of the abscess could relieve it. Abscesses near the surface could be healed by drainage with filiform tubes or stretching with brain forceps. Every operator naturally preferred his own method. Prof. Neumann had not had good results from his trial of Lemaître's filiform drains, which he had found insufficient. The temporary healing of an abscess must not be looked upon as final. There was insufficient material in the brain tissue for healing a large defect, and one part of the abscess cavity might heal as a solid mass while another part formed a cyst, which sooner or later—often years later—could be reinfected by an acute exacerbation which must be regarded as a relapse. Operation must be performed in such a way that the patient was not left a cripple, but on the other hand brain abscess was such a dangerous condition that the life of the patient must not be sacrificed by operating too timidly.

Diagnosis of Brain Abscess.

Mr. H. W. B. Cairns said that bad results in brain abscess were almost entirely due to faulty diagnosis. He would like to raise one point of operative technique. Success depended in the first instance upon the power of the brain to localise the infection. Whereas Macewen had used burrs for opening the mastoid, modern otologists used mallet and chisel. He wondered whether this was a factor in the results; whether perhaps the resistance of the abscess wall was partially broken down. On the whole the results were rather better in cases where the abscess did not arise from the ear.

Many unexplored cerebral cases went to post-mortem direct from the medical wards, but admittedly many of them only arrived at hospital when their condition was very bad. The blame for giving the benefit of surgical exploration to so few of these patients must be assigned to all branches of the profession. Symptomatically the cases were not yet clearly defined. The localising signs had been well established, but it was not so easy to remember the possibility of brain abscess in a patient who had relapsed into stupor after a short period of vomiting and headache. Cases were often diagnosed as encephalitis or cerebral thrombosis. Some mistakes were due to a neglect of ophthalmology and perimetry, but many cases showed little or no papillœdema. In most cases the temperature was subnormal. Brain abscess was often missed if it began during convalescence from some other illness. After a mastoidectomy, or even a mild attack of mastoiditis or frontal sinusitis, a patient might show some disturbance of convalescence, but as he was in bed under the best conditions for fighting infection a cerebral abscess might form, be well localised, and remain unsuspected. After apparent complete recovery and return to work he would be suddenly taken ill and die. All such cases of disturbed convalescence should be observed very closely over a long period. The onset of an abscess might be heralded by a Jacksonian fit, but was more often indefinite, especially if it arose from a neighbouring focus of infection. The localising signs had been well described; the difficulty was to elicit them. Repeated daily perimetry gave most valuable information, and it was possible to get charts from acutely ill patients if the right moment of intermission of symptoms were seized. The appearance of an homonymous quadratic defect clinched the diagnosis, and showed the level and progress of the abscess. The onset of a complete homonymous defect indicated immediate operation. Another useful diagnostic aid was X rays; abscesses often contained gas. The differential diagnosis from encephalitis, cerebral thrombosis, cerebral aneurysm, tuberculous meningitis, purulent pachymeningitis, purulent leptomeningitis, and serous meningitis could only be made at present by exploratory puncture. There was no risk of infection if the mastoid wound was sealed off with sheet gutta-percha. If pus was found directly the dura was nicked, if there was a large amount of subarachnoid cerebro-spinal fluid, or if a few drops of fluid were obtained from the lateral ventricle, then there was probably no abscess present. There was always considerable œdema round an abscess, and the ventricle was obliterated. Œdematous brain-tissue brought out by the needle could be distinguished from normal tissue; it was glistening, very soft, and yellowish-white. Purulent pachymeningitis might follow mastoiditis and cause signs and symptoms identical with those of abscess. Even at operation it might be overlooked, as the pus sank to the lowest part of the brain; the head, therefore, should be tilted when the dura was opened. Cerebral abscess might be confused with what was called by some serous meningitis and by others arachnoiditis, although neither term seemed a good one for a condition of hydrocephalus with some defect of absorption and possibly excessive production of cerebro-spinal fluid. It came on after acute or chronic mastoiditis, and there might be no demonstrable focus of infection. There was great risk of blindness, and a decompression should always be performed to save vision. Diagnosis must be carried out during treatment and the operation must take place in stages, as additional symptoms often arose after the first interference. Many problems depended on the accurate day-by-day observation of the patient.

Review of Cases.

Mr. J. S. **Fraser** gave an account of the 17 cases of temporal lobe abscess on which he had operated; six had recovered and 11 had died. Ten of them had been males and seven females, and most of them had been under 30 years of age. Nine of the abscesses had been on the right and eight on the left; only three of them had followed acute otitis media. The labyrinth had been functioning in 13 and not in two. The temperature had been subnormal in seven, normal in two, and raised in eight. The pulse-rate had been slow in five, normal in four, and rapid in eight. Ten had been drowsy or comatose on admission, and in four of these there had been attacks of delirium. The pupil on the affected side had been dilated in three cases and there had been sensory aphasia in four. Of the eight cases investigated by the ophthalmoscope, two had shown double optic neuritis. Six had had meningitis on admission, and five of these had died; six had developed meningitis after operation, and all of these had died; five had had no meningitis, and had recovered.

Pathology of Brain Abscess.

Mr. E. **Miles Atkinson** said that the essential point at issue was the route by which the infection travelled, and this depended on the anatomy of the cerebral vessels. Those descending from the cortex and those ascending from the base left between them a layer of white matter, just below the cortex, which was poorly supplied with blood. In this area the abscess first appeared. In 57 per cent. of cases which he had investigated the infection had been perivascular; he did not agree that the venous route was the usual one, although in some cases, especially lateral sinus thrombosis, clotting in a pial vein might spread back into the brain. Occasionally an artery might be caught up in the area of infection and a piece of its thrombus might break off as an embolus. The onset in these cases was typically apoplectiform. Once formed the abscess grew at the expense of the white matter, because the grey matter was more resistant, and always towards the lateral ventricle, because this was the direction of the vessels. In the cerebellum it grew at the expense of the white matter forming the core of a lobule, destroying it inward as far as the central mass. The term "capsule" was a complete misnomer, as the wall of a brain abscess was no different from that of an abscess anywhere else. In a very virulent infection there was no evidence of a protective mechanism at all, but only an acute spreading encephalitis. In this type localising symptoms occurred early, and the prognosis was bad. Where the abscess was chronic, and its wall thick, there was a greater chance of recovery if it could be drained, but the signs were fewer and more equivocal. Delay in operation might result in the formation of secondary abscesses.

Mr. W. S. **Sharpe** described a case which had shown the signs of abscess but had recovered under potassium iodide. He thought it possible to overdo surgical search for an abscess that was not there.

Cases.

Sir **James Dundas-Grant** showed a case of cerebellar abscess from thrombophlebitis of the jugular vein. This patient had been shown to the Section before. Opening of the lateral sinus, jugular vein, and jugular bulb had been followed by symptoms of abscess in the cerebellum; these had only been relieved by additional drainage behind the mastoid. Recovery had been satisfactory. He also showed a case in which vertigo had been cured by ossiculectomy, which had revealed cholesteatomatous masses pent up by the ossicles.

Mr. C. **Hamblen Thomas** showed a girl, aged 11, who had suffered for two years from intermittent earache without other symptoms. X rays had shown one mastoid acellular and the other highly cellular. After rest and treatment with antiphlogistine the patient had recovered.

Mr. T. B. **Layton** showed a case of recurring meningitis appearing first three weeks after septicæmic mastoiditis in a boy of 11. The second attack had appeared ten days after the first, and had been followed by steady recovery.

Mr. W. H. **Jewell** showed specimens from a case of actinomycosis of the brain in a woman aged 29. The symptoms had been frontal and occipital headache, photophobia, and pain in the eyes, with apathy and slow cerebration. The pupils had been unequal and active. Finally anæsthesia had supervened, followed by paresis of leg, arm, and lower half of face. The headache, apathy and fever, but not the paralysis, had been relieved by evacuation of extradural and subdural abscesses in the right Rolandic area, but 17 days later she had died.

SECTION OF ANÆSTHETICS.

At the meeting of this Section on Feb. 7th, with the President, Dr. R. E. **Apperly**, in the chair, a discussion on

Anæsthesia in Thoracic Surgery

was opened by Dr. C. **Langton Hewer**. Before 1914, he said, intrathoracic operations were regarded as a risk, but thoracotomy could now be performed with almost the same safety as laparotomy. This widening of the field of operation was largely due to improved anæsthetic technique. Dealing first with the preparation of the patient, Dr. Hewer said purgation of the patient before the operation was now considered undesirable. The drinking of as much fluid as could be comfortably taken for two or three days before the operation seemed to reduce post-operative vomiting and acidosis. Patients so treated did not show a dry skin and scanty urine, and the dilution of whatever poisons were present in their system was all to the good. He was not sure about glucose being useful, and he thought that large preliminary doses of hypnotics should be avoided; hyoscine gr. 1/100 and morphia gr. 1/4 sufficed for the average man, hyoscine gr. 1/150 and morphia 1/6 for a woman. After operation a larger quantity of warm saline could be given rectally while the patient was unconscious than after consciousness had returned. He gave 1¾ pints of saline, containing 5 per cent. glucose, while the wound was being closed. Operating table and bed at the time of the operation should be kept hot. As it was difficult to keep a large ward at the requisite warmth, he advocated the provision of recovery rooms, where patients could remain after operation until the temperature had returned to normal and the general condition was satisfactory.

Usually the subjects of thoracic operations were in poor condition; they might have phthisis, bronchiectasis, empyema, pulmonary abscess, or tumour. Operation caused oozing from large surfaces, with corresponding shock, and opening of the pleura meant a disturbance of the normal pressure relationships in the chest.

Requirements in Chest Operations.

In Dr. Hewer's opinion, the chosen anæsthetic for thoracic surgery should have the following characteristics: (1) It should have no depressant effect on the body, even though the administration might have to be prolonged. (2) It should have no harmful effect upon either normal or diseased lung. (3) It should not interfere with secretion in the respiratory passages, or abolish the reflexes, thus preventing evacuation of sputum immediately after operation. (4) Rapid recovery should be possible, and the anæsthetic should ensure adequate oxygenation of the blood, even when normal respiration was obstructed. Local analgesia had a useful place in the surgery of the chest, but high spinal block was not, in his view, justifiable. The pain after it was employed was greater than that which followed general anæsthesia, especially when intercostal nerves had been blocked. The power to cough was impaired for some time after a block, owing to temporary paralysis of abdominal muscles. Moreover, pleural shock might be responsible for an alarming amount of collapse. It must be remembered that injection of a minute quantity of novocain and adrenalin was capable of causing heart failure. He considered that injection of a solution without performing the aspiration test and without seeing that the needle point was always on the move, had led to deaths. When local analgesia was employed, no protection was afforded against respiratory obstruction, nor against collapse of the lung when the pleural cavity was opened. And the method was not good for young children, nor in cases where the injection would have to be made through septic areas.

Dr. Hewer was anxious that the good points of chloroform should be kept in mind. This was not irritating, it did not cause an increase of saliva and mucus, nor did it appreciably increase the depth of respiration. Indeed, he considered that chloroform had a definite place in thoracic surgery, especially in patients with a high respiratory obstruction. Ether permitted a light degree of anæsthesia to be maintained without risk of a cardiac failure. Often it was useful to give it by the open method to children who were too small to have nitrous oxide and oxygen properly. For extensive operations on the chest, however, he did not think ether was satisfactory, since it was liable to irritate the respiratory passages, and might thus increase the quantity of secretion there. Also vomiting was likely if the administration was prolonged. Of both paraldehyde and avertin it could be said that they interfered with the coughing reflex. Nitrous oxide and oxygen were in a different category, for nitrous oxide seemed to have no chemical effect, but acted physically by limiting the oxygen supply to the cells of the cerebral cortex. Moreover, this anæsthetic seemed to have no deleterious effects on either normal or diseased tissues. Tuberculous animals had had nitrous oxide and oxygen for 24 and 36 hours without aggravating their disease. This anæsthetic had many advantages for chest work, and if the patient vomited more than once immediately after regaining consciousness the cause was usually something other than the anæsthetic—perhaps the use of scopolamine and morphia before operation. The only real disadvantage in its use was poor muscular relaxation, and this was not very important in thoracic surgery. Ethylene and oxygen could be used in the same way, and with the same apparatus as nitrous oxide. But commercial ethylene had an unpleasant smell, and might cause nausea and vomiting; it was also highly explosive, and dangerous to use in the X ray room, or when lung tissue was to be cauterised.

Discussion.

Dr. I. W. MAGILL thought that all that was required in the way of anæsthetics in chest cases was local analgesia, supplemented, if necessary, by nitrous oxide and oxygen. When a pleural cavity had to be opened, the anæsthetist should be prepared for the accidental opening of the other pleural cavity, but Dr. Magill had seen this accident happen only once. And at the operation there was always the possibility of hæmorrhage from a large vessel, or the opening of a bronchus. It was a great advantage to have pneumothorax done before the operation. Local anæsthesia could be used for such operations as thoracoplasty. Nitrous oxide and oxygen was his choice for chest cases, using a face-piece instead of intubation.

Mr A. TUDOR EDWARDS, speaking as a surgeon, agreed about the great part played by improvements in anæsthetics in the advance of thoracic surgery. He thought that the smaller operations should always be done under a local anæsthetic; the same applied to empyema and usually to abscesses. Ordinary gas-and-oxygen anæsthesia was extremely satisfactory. Only when the mechanics of the chest were being altered was there need to induce a positive pressure. In thoracoplasty for tuberculosis or bronchiectasis the shock was greater than in other cases. Opening both pleuræ at the same time was seldom done, and it should not be attempted in substernal goitre cases.

Mr. J. E. H. ROBERTS said that in these chest operations even more important than the choice of the anæsthetic was the choice of the anæsthetist. Experience was essential. The operations could be carried out without shock where no infiltration of intercostal nerves was done.

Mr. T. P. DUNHILL pleaded for the use of chloroform in appropriate cases. Pathologists and coroners in London had done much to deprive chloroform of its rightful place in the armamentarium of the anæsthetist.

Dr Z. MENNELL said that for intrathoracic goitres, exploration of the mediastinum, and operations on the œsophagus the patient's safety and comfort, as well as the surgeon's happiness, were best served by light intratracheal ether. This was not so necessary in cases of definite disease of lung, and ether was contra-indicated in them. He emphasised the great importance of rapid operating in chest cases. He also added a plea in favour of using chloroform in suitable cases.

SECTIONS OF PSYCHIATRY AND NEUROLOGY.

MILDER FORMS OF THE MANIC-DEPRESSIVE PSYCHOSIS.

THE Section of Psychiatry held a meeting on Feb. 11th at which members of the Section of Neurology were invited to be present. Sir ROBERT ARMSTRONG-JONES, President of the Section of Psychiatry, took the chair, and Sir E. FARQUHAR BUZZARD opened a discussion on the Diagnosis and Treatment of the Milder Forms of the Manic-depressive Psychosis. He deplored that writers of text-books in general ignored the milder forms of the manic-depressive psychosis, and the distinction between the neurotic and psychotic forms of depression. In addition to mild forms which differed from the severe forms only in degree, there were many mild [illegible] which showed no history of preceding elation or depression. The ætiological significance of any possible source of anxiety must not be assumed without inquiring whether the alleged cause was still operative or whether its removal had produced improvement. There might, again, have been a history of restless activity and aggressiveness in ordinary affairs. The patient would complain not exactly of depression but of a detachment from reality and of a lack of interest and affection, for which he blamed himself. The absence of a concentration on one particular cause did not necessarily rule out psychotic depression. The depression was worst in the early morning and little influenced by environment; it was intensified by fatigue, and might lift unaccountably, especially towards the end of an attack. Fears of insanity or disease might be associated with it. Grief was not easily provoked, though some patients wept copiously without cause. Insight was good, but concentration, decision, and attention were bad. Psychotics were less troubled by insomnia than neurotics, but might resist sleep for fear of the depression on waking. They had more to say about their brains, and morbid and suicidal thinking was an almost constant feature. Suicidal attempts were more usually premeditated. Psychotic disturbance was always associated with physical disorder. The normal personality gave little diagnostic help, but a woman who became restless and domineering and then depressed was almost certainly of the psychotic type. Psychotics nearly always showed a high percentage of mental disorder, suicide, and alcoholism in the family history; the predisposition seemed to be directly transmissible, and alcoholism to be a direct result of the periodic psychosis. The milder the form, the more difficult the diagnosis, which in most cases required much time and care. No therapy seemed to prevent or shorten the attack. Most patients recovered if their sleep was secured and they were guarded against their friends' misguided efforts to arouse them. If the patient felt inefficient at work, he should be ordered complete rest on the physician's responsibility, but for some it was better to continue. The danger of suicide must never be forgotten, and congenial and tactful companionship should be provided. Physical well-being must be sought in every possible way. No disorder more demanded the guidance, comfort, and protection of an understanding physician.

Cyclothymia as a Biochemical Problem.

Dr. H. CRICHTON-MILLER objected to the term "manic-depressive psychosis" for the mild forms as too strongly suggesting the mental hospital and hindering the general recognition of the frequency of their incidence; he proposed to substitute "cyclothymia." The basic feature was variability of affective response independently of stimuli. The unstable temperament was a boat with insufficient keel; the cyclothymic was a pendulum. The difference lay in the degree of personal integration. The unstable patient was badly integrated, but the cyclothymic, though he had two contrasted integrations, each in its way imperfect, might in his normal phase show a well-integrated personality. The cyclothymic varied on either side of a norm, but in the case of dual personality one of the two phases constituted a true integration. In true cyclothymia the difference of response depended not on associative but on affective variation, and there might be a surprising degree of maladjustment before rational failure manifested itself. No theory explained cyclothymia and no treatment was fundamentally successful, however good the immediate results might seem. No physiological basis for the alternation had been discovered; the basal metabolism and blood-sugar were not changed. Nevertheless, the periodicity seemed to be a somatic rather than a psychological quality. The similarity of cyclothymic exaltation to alcoholic euphoria and of cyclothymic depression to that of intestinal absorption suggested a chemical factor, presumably acting on the thalamus. The reproduction of the cycle on a small scale in the menstrual cycle, and the fact that a relatively small proportion of patients led physiological sex lives, suggested that this biological factor might be hormonic; a rhythm-disequilibrium of hormonic function which tended to be self-limited, and which resulted in an endogenous toxæmia affecting thalamic activity in two contrasted ways and influencing cortical activity *only* in a secondary manner.

Dr. GEORGE RIDDOCH said that the depressed phase was more difficult than the exalted to differentiate from similar neurasthenic states, and that the previous speakers had been wise to stress it. He believed that emotional disturbances could precipitate the psychosis. The depression might lift during the day and sometimes after a night's sleep, but it had a certain persistency unlike that of the ordinary neurasthenic state. Retardation of physical as well as mental activity was diagnostically important; the psychotic was "furrow-bound." Whereas the neurasthenic projected his troubles, the psychotic took them on himself. A significant and frequent symptom was temporary hallucinosis, even in mild cases. An incautious physician might be led astray by the patient's complaint of other mental and emotional symptoms, and of fatigue, headache, and visceral disorders, and by his silence about his depression. There might be no history of previous attacks; the first sometimes occurred in middle age, especially in women. The history of a previous elation episode was significant, but the absence of it was not.

In treatment the environment was all-important, but much could be done by diligent attention and comprehension of the patient's troubles. The encouragement by relatives of unsuitable activities should be discountenanced, and during the depressed phase the patient was better away from them in an understanding atmosphere with suitable nursing. Dr. Riddoch said he should like to see a home endowed in the country, rather like the Cassel Hospital, where these patients could be cared for, understood, and kept from suicide—a task often requiring great vigilance. It was wrong to send mild cases to a mental hospital; they had full insight and ought not to be surrounded by insane patients and exposed to stigma. Sleep, food, and rest were important. Deep mental analysis was very dangerous, as introspection might plunge the patient deeper into his own misery.

Dr. HENRY YELLOWLEES held that there was a clinical entity to diagnose, and protested most strongly against the view that the difference between trivial downheartedness and psychotic depression was one merely of degree. The popular phase that melancholia was a "caricature" of depression was very misleading. He also looked with grave suspicion upon the term "mild melancholia." Although some forms were less severe than others melancholia, like pneumonia, was never a *mild illness*. Differential diagnosis from neurasthenia was a purely clinical problem and the crucial point in it was that, whereas the neurasthenic was a person of active emotional reactions who bewailed the limitations which his illness imposed upon him, the melancholic, whatever he might seem or be called, was the reverse. The understanding of Kraepelin's point of view, that the emotional state was secondary to the fundamental volitional disturbance, was essential. Of almost equal importance was the recognition of the cardinal neurasthenic symptom—excessive fatigability—and the use of the final touchstone that the neurotic had true insight and the psychotic had not. If he had, however mild his illness, he would not be a psychotic. The physician needed an intimate personal knowledge of the natural history of the disease.

Mild hypomania or elation had the distinction of passing undiagnosed more often than any other condition. The general inability to regard these cases as a whole was vividly illustrated in legal proceedings. The procedure was invariably the same; isolated acts of the patient were described one after the other, and the witness was asked of each one, "Is that a sign of insanity, Doctor?" Dr.

Yellowlees waited almost in despair for someone to protest publicly against this imbecile question, and to insist upon describing and explaining the patient's mental state as a whole, and in his own way.

The fact that the manic-depressive psychosis had to run its course hardly justified the statement that there was no treatment for it. Wise management—a better word than treatment, especially in the depressant phase—depended upon a proper conception of the illness as a whole. Melancholia was ipso facto not amenable to psychotherapy; neurasthenia was amenable to psychotherapy in general, and especially to analysis. Psychotherapy, especially hopeful suggestion, might be a valuable adjunct to the treatment of melancholia; but its modern analytical developments, although they explained temptingly many of the mechanisms of the disorder, could never cure. A frequent and ominous phrase in the newspaper reports of inquests was, "His doctor had been treating him for depression." Practical physicians should do all in their power to refrain from treating patients for depression with such a result as an inquest.

The Frequency of Mixed Cases.

Dr. W. R. **Reynell** said that depression might occur several times before the complete cycle was established. It was not always of the same kind, but might take various forms such as remorse, fear, or resentment. Mild cases might shade off into anxiety or instability, and hard-and-fast classification was impossible, as many cases had mixed symptoms. Some manic-depressives were readily fatigable, others developed fainting fits on the border-line of epilepsy; some migraine subjects occasionally had sudden attacks of depression without headache, which resembled the depressive phase of the psychosis. All the periodic psychoses and neuroses were related genealogically, and in their manifestations. The history of mental disorder in 80 per cent. of relatives showed some structural defect. The occurrence depended on the psychotic potential, without which no stress could produce psychosis. If, however, the patient had an inherited tendency to psychosis, an attack could be precipitated by exogenous or endogenous causes. Neurasthenics often showed cycles of euphoria and depression, and might develop into typical manic-depressives. In most cases, in short, the ætiology was mixed. In treatment, the greater the psychogenic factor the stronger the indication for psychotherapy; the greater the somatic factor the more should the physician rely on rest and physiotherapy. The nature and depth of the psychotherapy depended on the individual.

Dr. **Helen Boyle** stressed the connexion of the disease with excessive or defective thyroid secretion. The condition might often originate, she said, in adolescence, fear being a potent activator of the thyroid, and preventive glandular treatment should be applied at this age. Normal thyroid function had a cyclothymic rhythm. It was important that the patient should have occupation well within her powers, but absence of stress might itself sometimes constitute stress. Dr. W. H. Stoddart had recommended the "regular way," so that the patient could have adequate knowledge of the alteration before the mental and nervous fit became too severe. Insight was usual in the normal state. Contact with a trusted doctor was invaluable, and some form of hydrotherapy might be of benefit.

Dr. E. W. **Neill Hobhouse** pointed out the similarity of the symptoms in early general paralysis to those of mild manic-depressive psychosis; myxœdema he said, might occasionally cause confusion, but it was often possible to be misled by meningovascular syphilis. This sometimes produced mild depression, loss of interest, and occasional outbursts of temper, but the history and the improvement under specific treatment should be sufficient to determine the diagnosis. Some cases of manic-depressive psychosis, mostly women of a definitely efficient type between 25 and 35, resembled hysteria in excitability and a rather noisy combativeness, but did not feel ill and did not desire pity nor seek to attract attention. Another possible source of confusion was hyperthyroidism in the absence of goitre. If these cyclical cases were to be recognised by the practitioner they must be recognised by the student, and they would not be until the term "manic-depressive psychosis," which only suggested the padded cell, was abolished in favour of "cyclothymia."

Dr. E. B. **Strauss** commented on the apparent decrease in the incidence since his early years; the diagnosis had then been too comprehensive. Depression might be the most prominent symptom in a number of other conditions. There was a certain definite connexion between manic-depressive psychosis and allied conditions and the pyknic physique. In addition to the other diagnostic data the measurements and physical type should be ascertained; search should be made for schizophrenic stigmata and the motoricity determined. If the patient had had previous attacks of depression or was usually over-boisterous, and if his physique was predominantly pyknic, the diagnosis was absolutely certain unless the picture was complicated by factors such as arteriopathy and syphilis. Persons with a predominantly schizoid make-up could not develop manic-depressive psychosis, and the physician should suspect catatonic schizophrenia or a mixed psychosis. Pyknic and correlated constitutions could modify the course of schizophrenia to cause confusion. Reactive depression was one of the commonest forms of depression and one of the most frequent sources of error; it was caused by an intolerable situation, and was allied to true neurasthenia or prison psychosis, and was not endogenous or constitutional in the sense of the manic-depressive psychosis. It affected schizoid rather than cycloid types. Institutional treatment was desirable even for the mildest attacks of manic-depressive psychosis. In women at the climacteric a really active ovarian preparation sometimes exerted a remarkable effect.

The **Chairman**, answering Dr. Riddoch, praised the licensed houses under the special hospitals. A very great point in treatment was the "restitutio ad integrum"; no manic-depressive patient became demented. The sudden onset was pathognomonic. There were no hallucinations and no delusions.

Sir **Farquhar Buzzard** replied.

MEDICAL SOCIETY OF LONDON.

At a meeting of this Society on Feb. 10th, with Mr. **Donald Armour**, the President in the chair, a discussion on the

SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS

was opened by Dr. **Gustav Maurer** (Davos). He dealt with the surgical treatment of adhesions which prevented proper collapse of the lung after artificial pneumothorax, and which prevented permanent cure, according to Gravesen and the Matsons, in 37 per cent. of cases. Great service had been rendered, he said, by Jacobæus, who, in 1910, had invented the first practical method of dividing adhesions by a galvano-cautery after discovering their position with a thoracoscope similar in construction to a cystoscope; but although he had obtained improvement in 66 per cent. of patients, cure could never be guaranteed because of the complications of empyema and tuberculous exudate. Exogenous infection could be avoided by care, but endogenous infection was an ever-present danger, because three-quarters of operable adhesions contained lung tissue, the parenchyma losing its vitality through the perifocal inflammation, and becoming drawn up into the pedicle on the induction of pneumothorax. Most adhesions were composed, in varying proportions, of three types of tissue: parietal pleura plus endothoracic fascia; a fibrotic bridge, or the symphysis between the parietes; and the lung pedicle. Owing to the great difficulty of distinguishing the connective tissue from the parenchyma by sight, adhesions were best classified for practical purposes according to their shape :—

(1) Very thin elastic adhesions; division did neither harm nor good.

(2) Adhesions with a broad thoracic insertion and a fibrotic, inelastic symphysis; the parietal pleura was projected in a tent shape. They were rare.

(3) Adhesions with a conical pulmonary insertion and a dense symphysis of long-standing; the devitalised lung was drawn into a pedicle. They were fairly common, and their division was the cause of most empyemata, but if no complications ensued they gave the best therapeutic results.

(4) Hour-glass adhesions, with both insertions expanded, and a fibrotic bridge between. There was less risk of empyema than in the third class, and equal benefit from division. Most important adhesions belonged to this class.

The thicker the adhesion the more serious the condition and the nearer the parenchyma approached the chest wall. The term "division" really implied unskilful technique, and it was absolutely necessary to enucleate adhesions from the chest wall, where they consisted, with rare exceptions, solely of connective tissue. This could not be done with *Jacobæus's* instrument, nor its modifications, on account of the vascularity of the adhesion and the proximity of intercostal vessels. Attempts had been made to replace the galvano-cautery by cutting diathermy, but the strong current required might easily cause deep coagulation and empyema. Dr. Maurer then exhibited his apparatus, and described his own method with high-frequency currents of 0·1 to 0·3 ampères, which only produced a coagulation zone 2–3 mm. wide. For very expanded insertions he used alternate diathermy and galvanic current on the same electrode, with foot control. Local anæsthesia was indispensable, and 0·4 per cent. novocain was given through a long needle. He could enucleate short membranes as thick as a finger, crowded or crossing one another, and rope-like adhesions as thick as a humerus. He held fast to the two-puncture method.

He exhibited water-colour pictures of adhesions and X ray films of cases.

Surgical Methods of Collapse, Accessory or Alternative to Artificial Pneumothorax.

Mr. H. **MORRISTON DAVIES** said that sanatorium treatment, though the simplest, might be inadequate because the disease was so acute, the resistance so poor, or the secondary changes so extensive that its healing effect could not take place in time. If only one lung was involved its collapse would achieve the desired result, but collapse was not always easy.

The commonest indication for operations—phrenic evulsion, thoracoplasty, multiple neurectomy, and *extrapleural pneumolysis*—was the failure to secure complete collapse by artificial pneumothorax. Evulsion had almost entirely superseded simple section because it destroyed the connexion of the accessory phrenic with the main nerve. The operation was done under local anæsthesia, except in young children. As a consequence of the resulting paralysis of the diaphragm, spasm disappeared, respiratory movements were abolished or replaced by paradoxical movement, and the dome of the diaphragm rose. The lung was thus freed from constant strain and partially collapsed, reducing the drag on the mediastinum and relieving the symptoms. The indications for phrenic evulsion were: (1) Basal tuberculosis; it was rarely successful in basal bronchiectasis. (2) Chronic basal effusion with thickened pleura. (3) Generalised tuberculosis when artificial pneumothorax had failed. (4) For the relief of symptoms such as pain, dragging, tachycardia, and dry, irritating cough. (5) As an accessory to artificial pneumothorax when the base of the lung was adherent. (6) As a preliminary to thoracoplasty to reduce the number of ribs needing excision. (7) To prevent the development of bronchiectasis after unresolved basal pneumonia.

Two essentials of thoracoplasty were that the posterior line of division of each rib should be made at the level of the transverse processes and that the excision should include the first rib. These ensured that the ribs dropped and tilted downwards so that the lateral cut ends became approximated to the spine. This produced very considerable collapse of the lung, even if only the first eight, seven, or six ribs were excised. A thoracoplasty limited to the first four ribs was as efficacious as, and preferable to, apicolysis. The collapse, though *partial*, was constant, and the operation produced no crippling deformity. Its indications were those for artificial pneumothorax, but its contra-indications were much more severe. It was only indicated in preference to any other line of treatment in cases of advanced chronic unilateral fibrotic tuberculosis. An active lesion in the opposite lung was a complete contra-indication except in cases of alarming recurrent hæmorrhage. Other contra-indications were tuberculous enteritis, cachexia, a failing heart, albuminuria, and diabetes, but not tuberculosis of the larynx unless there was considerable œdema or involvement of the epiglottis. Thoracoplasty should be performed when a pneumothorax failed to control the symptoms, especially in fibrotic and hæmorrhagic cases, or when the lung was re-expanded; and when a pyothorax was not controlled by an oleothorax.

Multiple intercostal neurectomy gave slight collapse and apparent benefit in some cases, but the number was yet too few for any conclusion. Apicolysis was best performed with a pedunculated graft of pectoralis major or the mamma; paraffin might produce an extrapleural effusion which found its way into the tissues, and fat was apt to degenerate. Mr. Davies illustrated his paper with X ray films.

A Single-puncture Method.

Dr. F. G. **CHANDLER**, while admiring Dr. Maurer's technique very greatly, preferred—in common, he said, with many other workers—to perform the whole operation through one puncture. Davidson, of New York, had invented a successful operating thoracoscope, which combined telescope, lamp, and electrodes in one instrument, but it was large, it had to be moved to and fro in manipulation, and, being oval in section, its rotation opened up the tissues and increased the liability of sepsis. Dr. Chandler had devised[1] a thoracoscope which involved only one puncture, was quite small, and worked through a cannula no larger than that of Jacobæus. It was fitted with a ball which pressed against the chest wall and prevented emphysema, and had only one electrode. Diathermy current was employed and controlled by a foot switch; no smoke was produced. The whole instrument could be boiled. It had a large coagulating electrode at its extremity through which the cutting hair was pushed, and by which it was stabilised.

Stereoscopy might give an idea of the type of the adhesion, but would not localise it. At Victoria Park the patient was examined on a screen and rotated to give an all-round view, and an X ray picture was taken, centred over the adhesion to minimise distortion. A favourable intercostal space was then chosen on a skeleton. The disadvantages of this method were that the adhesion might be of an unexpected shape, and that it was impossible to tell whether it contained lung tissue or not, especially when pleural effusion was present. He wished that Dr. Maurer had said more about localisation. He was experimenting with an instrument by which lipiodol could be injected into the adhesion. Oleothorax maintained a permanent collapse, and prevented the type of adhesion caused by the deposit of fibrin in a costophrenic sinus and the drawing together of the two pleural layers. Olive oil was used, with an admixture of 5 per cent. of an antiseptic called gomenol. The chief indication was obliterative pleurisy.

Discussion.

Mr. **TUDOR EDWARDS** said that he had used a modification of the Jacobæus instrument, and had not found the difficulties which Dr. Chandler had mentioned. He agreed with Dr. Maurer's insistence on dividing the band as close to the pleura as possible and on the necessity for a local anæsthetic. At the apex, however, it was dangerous to divide very close to the pleura as the innominate vein was likely to be injured. He was not quite happy about the effect of the partial thoracoplasty mentioned by Mr. Morriston Davies. The amount of collapse seemed very small in comparison with the amount of rib removed. He also had been very disappointed with apicolysis and had only found it useful where cavities remained at the apex after a more or less complete thoracoplasty, owing to the thickness of the wall or the softness of the lung below.

---

[1] See THE LANCET, Feb. 1st, p. 232.

Mr. J. E. H. ROBERTS said that the mixed infection empyema originated in the lung, but when it followed adhesion and consisted of a simple staphylococcus or streptococcus it was often the result of faulty asepsis or a contaminated anæsthetic. From his experience of the technique in other countries he was surprised that the incidence of empyema was so low.

In phrenic avulsion it was possible to tear lymphatic vessels in pushing aside tuberculous lymphatic glands and to give rise to local effusions in the neck. He preferred a two-stage complete thoracoplasty to the partial thoracoplasty advocated by Mr. Davies. That immobilisation was very important was proved by the results of neurectomy of the intercostal nerves performed by Alexander. In place of apicolysis he preferred an operation which he had learnt from S.W. Harrington of the Mayo Clinic; the ribs over the cavity were resected subperiostially and gauze was packed in against the mobilised periosteum, underneath the skin and overlying muscle. Pressure was exerted upon the outside of the lung by the collapsed periosteum and maintained by the regeneration of the rib. This method avoided the use of a foreign material, which might give rise to necrosis.

Reply.

Dr. MAURER, in reply, said that the main argument against the one-puncture method was the general impossibility of localising adhesions accurately enough to introduce the cautery at right angles to the thoracic insertion. The local anæsthetic could not cause a mixed empyema; he had not had one in 400 cases.

Mr. MORRISTON DAVIES asked why, if Mr. Roberts approved of the results of immobilisation by Alexander's intercostal neurectomy, he should not approve of the local thoracoplasty for the local lesion. It did the same work and gave still more collapse.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 1ST, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 354 (last week, 313); scarlet fever, 3035; diphtheria, 2051; enteric fever, 38; pneumonia, 1265; puerperal fever, 58; puerperal pyrexia, 98; cerebro-spinal fever, 15; acute poliomyelitis, 2; acute polio-encephalitis, 1; encephalitis lethargica, 22; continued fever, 1; dysentery, 10; ophthalmia neonatorum, 108. No case of cholera, plague or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Feb. 4th–5th was as follows:—Small-pox, 558 under treatment, 28 under observation (last week, 523 and 29 respectively); scarlet fever, 2371; diphtheria, 2768; enteric fever, 18; measles, 971; whooping-cough, 106; puerperal fever, 31 (plus 19 babies); encephalitis lethargica, 121; "other diseases," 17. At St. Margaret's Hospital there were 20 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 3 (0) from enteric fever, 48 (24) from measles, 14 (4) from scarlet fever, 35 (4) from whooping-cough, 45 (13) from diphtheria, 47 (15) from diarrhœa and enteritis under two years, and 57 (7) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever were reported from West Hartlepool 2, Stockport 1. Measles accounted for 8 deaths in Manchester, 2 each in Wigan and Sheffield. There were 8 deaths from diphtheria in Liverpool and five from diarrhœa. Influenza was credited with 6 deaths in Birmingham, 3 each in Manchester and Leeds.

The number of stillbirths notified during the week was 297 (corresponding to a rate of 47 per 1000 births), including 41 in London.

FATAL CASE OF VARIOLA MINOR IN LEICESTER.

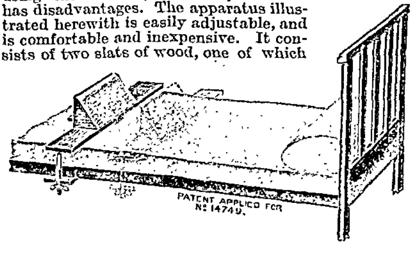
As we noted last week, small-pox was mentioned as a cause of death in a case assigned to Leicester. Dr. C. Killick Millard, medical officer of health, writes: "As this is the first death from 'small-pox' in Leicester for over a quarter of a century (the last death having occurred in June, 1904) it calls for some comment. The victim was a weakly baby, bottle fed, the youngest of a large family, who was infected by an overlooked case in the family within a few days of birth. The child was taken ill on Jan. 13th; the eruption appeared on the 15th, and the child was admitted to hospital, together with its mother and elder brother, both suffering from the disease, on the 18th. The *child was then in an obviously serious condition.* There was a fairly abundant rash and the child had been refusing food and suffering from vomiting and diarrhœa for the last few days. It died the day after admission.

"This case illustrates what is now well recognised—namely, that variola minor, although ordinarily a non-fatal disease, may occasionally, like varicella and other non-fatal diseases, prove fatal when it occurs in very young infants."

New Inventions.

BED FOOT-REST.

THIS is a simple apparatus which will enable a patient to be kept in the sitting position whilst in bed. Up to the present the means of doing this has been by using the ordinary "Donkey" which has disadvantages. The apparatus illustrated herewith is easily adjustable, and is comfortable and inexpensive. It consists of two slats of wood, one of which is placed under the iron frame of the bedstead, and the other, to which the foot-piece is fixed, is placed over the mattress. These two slats are clamped at each end with screw clamps. A pillow is then folded over the foot-piece.



Messrs. Allen and Hanburys, Ltd., 48, Wigmore-street, London, W., are the makers.

HUGH F. EALAND, L.R.C.P. & S. Edin.,
L.R.F.P.S. Glasg.

A ROMAN CATHOLIC HOSPITAL.—The sisters of Our Lady of Compassion, who established a Nursing Home in the Lambeth Ward some 30 years ago, have purchased for £30,000 the freehold of the property and intend to rebuild the premises and establish a hospital at a total cost, including that of purchase, of £100,000.

Reviews and Notices of Books.

SURGICAL DISEASES OF CHILDREN.

Third edition. By SAMUEL WALTER KELLEY, M.D., LL.D., F.A.C.S., Member, Senior Staff, St. Luke's Hospital, Cleveland, Ohio; Major and Brigade Surgeon, U.S. Volunteers. London: Henry Kimpton. 1929. 2 vols. Pp. 1374. 63*s.*

AMERICAN physicians have devoted much time and ink to "pediatrics," but it is clear from the preface to these two handsome volumes that the surgery of childhood has received much less attention. Dr. Kelley speaks of his work as a pioneer endeavour when the first edition appeared 20 years ago. The volumes in their present form are well able to bear comparison with any British work on the subject. The book has evidently been completely rewritten, and 300 new illustrations have been added, so that the publishers have justification for their claim that it is practically a new book.

The author takes a wide view, and encourages his readers to treat the child and not only the disease. In this connexion he devotes space to drugs, feeding, and stimulants, and lays emphasis on the general care of the patient. Anyone who expects to find striking differences between American methods and our own will be disappointed. The book conforms in most respects to generally accepted teaching on this side of the Atlantic; there is nothing startling, but the presentation is sane, sound, and well balanced. In one or two instances the author is dissatisfied with present-day procedure, but even here it seems that his own countrymen are offenders no less than ourselves. He presents a strong case for more frequent operation on depressed fractures of the cranial vault in babies (p. 606), and a well-argued and interesting plea for immediate decompressive operations when intracranial birth hæmorrhage has been diagnosed (p. 611, *et seq.*). Lumbar puncture is now the approved procedure in America, but Dr. Kelley maintains, with good reason, that though the mortality in operated cases is 50 per cent., "the alternatives are so dreadful that this should not deter us" from a more radical attack when necessary. In England we see many older cerebral diplegics, but they very rarely find their way to hospital within a few hours of birth. The obstetrician and the general practitioner could remedy this, and Dr. Kelley looks forward to the time "when professional opinion will demand operation in all cases of depressed bone or intracranial hæmorrhage in the new-born whenever there are enough symptoms to make a diagnosis."

Harelip and cleft palate receive full notice, although the author is a little vague about the best age for operation; he seems to favour closure of the lip at about three months and of the palate at six to nine months. He believes that strapping plaster is useful as a preliminary to operation on harelip and some of his photographs seem to bear this out. Cleft palate is closed by Langenbeck's operation. Brophy's procedure is thought to carry a high mortality and to give bad functional results, whilst Lane's flap operation is scarcely mentioned. In the section on surgical tuberculosis the teaching is sound. Non-operative treatment of bones and joints is preferred, but under certain conditions operation is not only justifiable but imperative. The author sometimes uses the Paquelin cautery as a counter-irritant in joint tubercle and then applies plaster-of-Paris. This seems a dangerous proceeding, and not to be commended on general principles. Nearly all the sections on orthopædic subjects are good, both instrumental and operative treatment being fully considered. Several references are made to gonococcal arthritis, which is rare amongst British children, but may be commoner in America. Volkmann's contracture is not particularly well presented; the condition is important enough to be illustrated, and Max Page's operation deserves mention. In considering the abdomen, Dr. Kelley makes it clear that appendicitis in children brooks no delay, and immediate operation is the general rule; colostomy for "megacolon" may sometimes prove sufficient, and, of course, has a much lower operative mortality than colectomy. Intussusception is dealt with on standard lines, though the author devotes a good deal of space to injection methods. Chest surgery is mainly represented by empyema, to which 23 of the 35 pages in the chapter are devoted. Surgery of the air passages receives two chapters, including a valuable article on intubation, which is considered with unusual wealth of detail.

Many of the photographs and diagrams are excellent, and it appears that the author is personally responsible for most of them. The series photographs, in which we see the same condition on four or five separate occasions, are particularly interesting. The book is admirably printed and produced.

A COURSE IN PHYSICS.

For Medical and Dental Students. By RICHARD ABLETT, M.Sc., Lecturer in Physics, University of Liverpool. With a foreword by L. R. WILBERFORCE, M.A., Professor of Physics in the University of Liverpool. London: Humphrey Milford, Oxford University Press. 1930. Pp. 249. 8*s.* 6*d.*

THERE are several well-known volumes containing the information on physics necessary for the preliminary examinations in medicine and such specialties as dentistry and pharmacology, but this is not to say that there is no room for such an excellent little textbook as the one now before us. It is short, accurate, well-produced, and by no means dear. At the same time the brevity of the book, which certainly is one of its merits, may have been obtained sometimes by the sacrifice of a good deal which the student will have to know before he can follow the teaching, and some of which might have been recalled to his mind. It is true that in the preface the author points out that the number of university students who intend to pursue a medical course, and who before entry had no instruction at school in physics, is rapidly decreasing, but from the very beginning of the book it is clear that Mr. Ablett attributes to his audience considerable familiarity with the subject. Given the necessary preliminary knowledge needed to make reading of the book of practical use, the author may be congratulated on having produced a sound and valuable treatise. Difficult sections under the general heading of electricity are notably clear, and such sections can be used as a test, being so often hard of comprehension in small manuals. The author's claim to be teaching physics throughout as physics, while bearing in mind the value of applications to and illustrations from medical practice, is substantiated, and the subject made real and living to the medical student, if only he is sufficiently grounded to assimilate the teaching—a doubt which will remain in our mind.

CREATINE AND CREATININE.

Monographs on Biochemistry. By ANDREW HUNTER, M.A., M.B., F.R.S. Can., Professor of Biochemistry in the University of Toronto. London: Longmans, Green and Co., Ltd. Pp. 281. 14*s.*

THESE monographs on biochemistry are among the most useful series of publications in modern biochemical literature, since they make it possible for readers to keep pace with the most advanced views of this rapidly growing science without having to wait for a new edition of some large text-book. The monographs not only contain far more detail about facts and methods than would be possible in one volume, but they are authoritative treatises. Dr. Hunter's contribution to the series is divided roughly into two halves, the first four chapters being a compilation of all known facts, and the last five dealing rather more with theories and interpretation. The first chapter provides a brief history of creatine and creatinine from the date of Chevreul's first discovery of the former in 1832, ending with some of the controversies of recent times regarding the structure of these substances. The second chapter is a long one and deals very fully with the general chemistry and the derivatives of creatine and creatinine. Then follow various methods of preparing these substances from different sources, and methods of quantitative determination. Chapter 4 is on the distribution of creatine and creatinine in biological substances, and includes some comprehensive tables. The next two chapters deal with the output, metabolism, and origin of creatinine, while the last three are devoted to studies of the physiology and origin of creatine, creatinuria being the subject of one of them. The author deserves congratulation upon the excellent bibliography, which is almost as complete as it could possibly be, and is the more valuable since nearly every reference has been made from the original paper.

Physical Diagnosis.

Diseases of the Chest and the Principles of Physical Diagnosis. Fourth edition. By George William Norris, A.B., M.D., Professor of Clinical Medicine in the University of Pennsylvania; and Henry R. M. Landis, A.B., M.D., Sc.D., Professor of Clinical Medicine in the University of Pennsylvania. London: W. B. Saunders Co., Ltd. 1929. Pp. 954. 45s.

This well-known text-book deals with the physical diagnosis of the heart and lungs in health and disease. The first 295 pages are devoted to a detailed account of the respiratory and circulatory systems in health. The teaching of physical signs and methods of examination applicable to the normal subject has been sadly neglected, though the importance of such a study is becoming more and more recognised; the student and practitioner will find a full description of modern methods of examination, including a chapter on the electrocardiograph from the pen of Dr. Edward B. Krumbhaar. X ray examination, in our view, is dismissed too briefly as merely a control to other methods of diagnosis; important as these general methods are, X ray will frequently disclose disease which was quite unsuspected, even after the most careful examination by other means. In this book are included many excellent skiagrams showing various morbid conditions.

An article by Dr. Louis H. Clerf on the value of the bronchoscope in diseases of the bronchi and lungs is useful. Whilst describing the many indications for bronchoscopic examination, the author points out its limitations, and notes that only the larger bronchi can be examined by this method. The third and fourth parts of the book deal with diseases of the intrathoracic viscera, the signs, symptoms, and morbid anatomy of the various conditions being fully described. To the practitioner and senior student interested in intrathoracic disease this work will be of great value.

Zoological Science in Persia.

The Zoological Section of the Nuzhatu-l-Qulub of Hamdullah Al-Mustaufi Al-Qazwini. Edited, translated and annotated by Lieut.-Col. J. Stephenson, C.I.E., M.B., D.Sc., F.R.C.S., I.M.S. (ret.), Lecturer in Zoology, Edinburgh University. Royal Asiatic Society. Pp. 100.

The interest of this very early Persian work, which has been translated and annotated with great care by Colonel Stephenson, lies in the fact that it is a record of the actual state of zoological science in Persia during mediæval times. It is a section of a much larger work by the same author which was essentially a popular dictionary of science, concerned with a description of the animals then known and their relationship to man. One gathers that the author was not himself a scientific observer or field naturalist, but rather a compiler of facts already recorded by others. The work provides a fairly comprehensive idea of the materia medica of the day, at least so far as drugs of animal origin were employed. The short description of the characteristics of each animal is followed by a list of the medical uses of its various organs.

The diseases coupled with these drugs are even more interesting, since many of them are easily recognisable, the commonest maladies being the eye-troubles associated with arid, tropical climates, leprosy, malaria, and tuberculous glands. The removal of superfluous hair is a subject which evidently attracted considerable attention. A formidable list of depilatories are recommended, among which horses' sweat, porcupines' bile, tortoise and rhinoceros blood and eggs, leeches' and bats' dung seem to have been popular. An equally long list of medicines reputed to cause the growth of hair is given, but it is obvious that aphrodisiacs were the primary concern of the medicine man of the day and there is hardly an animal mentioned whose testicle when ground up and mixed with honey was not regarded as a sovereign remedy for restoring sexual power to the aged or impotent. Cantharides is mentioned as a violent poison, but curiously enough its aphrodisiac effect does not appear to have been suspected. For the most part the remedies recommended are of a magical nature and seem to have no reasonable foundation. The tradition of many of them still lingers in remote parts even of this country, and some are still practised—for example, the use of cobwebs in staunching the flow of blood from a wound. Some of the remedies advised must have led to results worse than those attributable to the disease.

The translation of this work will no doubt be of considerable interest to oriental scholars and those interested in early medical history. The original Arabic from which the translation was made is printed in full at the end of the book.

Possession, Demoniacal and Other.

By T. K. Oesterreich, Professor at the University of Tübingen. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1930. Pp. 400. 21s.

This survey of the history of demoniacal possession among primitive races, in the Middle Ages and in modern times, discusses also artificial and voluntary possession, and, in ranging from prehistoric dates to the present time, takes note of manifestations all the world over which seem to fall within the scope of the title. The translation is from the German, although for certain notes an authorised French version has been employed. The book is the result of investigations which have been published in the *Deutsche Psychologie,* but the subject matter has been considerably extended here since the original publication. The copious quotations, in respect of which careful bibliographical references are made, are responsible for the size of the volume, while in this way the literature essential for pursuing any of the indicated lines of thought further is brought to notice.

Prof. Oesterreich quotes the New Testament, Lucian, and the Acta Sanctorum in the introductory chapter, and goes on to describe the external signs of possession, describing a condition when the sufferer's organism appears to be "invaded by a new personality. . . . as if governed by a strange soul." Once this is granted, the wealth of information in respect of the external signs of possession, the subjective state of the possessed, and the manner and methods of exorcism become removed from the category of curious narratives to be ranged under that of psychological evidence, but, whether or no this is the view which Prof. Oesterreich would have us take, the ethnological interests of the book remain exactly the same. A complete disbelief in the existence of such a thing as demoniacal possession would not make the collation of stories less informative and instructive as evidence of human thinking and manners. A particularly interesting chapter is that on Shamanism, a designation for artificial and voluntary possession amongst primitive people where Mr. and Mrs. C. G. Seligmann, Frobenius, Tremearne, and Mariner are freely quoted from. A further section treats of voluntary possession as seen among higher civilizations, and here there will be found an elaborate account of the ritual accompanying the delivery of the Delphic Oracles as well as the arguments for belief in the veritable existence of the Sibyls. Much of the literature, citations from which occupy so large a proportion of the author's pages, will be familiar to medical men interested in psychology and neurological pathology, but a number of passages are set out from authors whose scientific views will be unknown to most readers.

The human race is certainly seen in a fantastic light in the discussion of the relationship of possession to the manifestations of spiritualism, or the phenomena of hysteria, and in many places Prof. Oesterreich points to paths of research which might be followed.

EVOLUTION OF THE EARTH AND MAN.

By Twelve Authors. Edited by Prof. G. A. BAITSELL. New Haven: Yale University Press. 1929. Pp. 476. With 83 figures. 22*s.* 6*d.*

THE scope of this book is well indicated by its title—it is an account of the origin and progress of the earth and of those that dwell therein. Written by 12 different authors, it naturally lacks the coherence of a well-ordered tale, but between them the chapters seem to cover most of the ground, and each one by itself has the advantage of an expert's knowledge and experience. There is a certain amount of jargon, for instance, the "heavings of the earth's broad breast" which Prof. Lull brings into his account of vertebrate evolution; the frontispiece, too, is more fit for the movies and may give a wrong idea about a serious and very readable book. As the Laureate has lately reminded us, his evolutionary connexion with animals is the most significant fact about man in all his aspects and relationships. It is therefore impossible to pick out any of the chapters as having a particular importance for modern medicine; they are all germane. Immediately, perhaps, Prof. Huntington's summary of his conclusions about the bearing of climate on human life has the greatest hygienic interest, and it is certainly cheering to read once more that "there is no climate which excels that of south-eastern England in its healthfulness and its stimulus to vigorous physical work, hard study, and creative mental activity." Londoners evidently have something to live up to.

PUBLIC HEALTH AND HYGIENE.

A Student's Manual. By CHARLES FREDERICK BOLDUAN, M.D., Director, Bureau of Health Education, Department of Health, City of New York. London: W. B. Saunders Co., Ltd. 1929. Pp. 312. 12*s.* 6*d.*

THIS manual endeavours to cover in relatively small space the whole range of public health activity. It is divided into five sections, dealing with general introductory considerations, important communicable diseases, other important preventable diseases and conditions, community hygiene, and prevalence of disease. The book contains a mass of detail, but little balanced assessment of the value of the various lines of procedure or the theories on which they are based. The terminology is needlessly unscientific for a book intended for medical students, and such important problems as immunity are dealt with in rather a scrappy way. Vitamin D is not mentioned in connexion with rickets. The chapter on food poisoning gives the wrong impression that food containing the bacteria or toxins responsible for such poisoning is almost always offensive in taste or smell; the view expressed that *B. paratyphosus* is sometimes responsible for food poisoning is now discredited; *B. aertrycke* is not here mentioned in this connexion. The book is copiously illustrated. On the whole, the illustrations are well produced and apt, though some of them, notably Fig. 100, with its caption "Gardez l'eau," are not of great value. If the author had been a little less ambitious his book might have been useful for the training of nurses and other non-medical workers; it is not very suitable for medical students.

MAMMALIAN PHYSIOLOGY.

A Course of Practical Exercises. Second edition. By E. G. T. LIDDELL, D.M., Fellow of Trinity College, Oxon.; and Sir CHARLES SHERRINGTON, O.M., M.D., D.Sc. Cantab., F.R.S., Waynflete Professor of Physiology in the University of Oxford. Oxford: At the Clarendon Press; London: Humphrey Milford. 1929. Pp. 162. 15*s.*

THE merits of the course on Mammalian Physiology by Prof. Sherrington have long been gratefully recognised by all who have worked on this subject, and we welcome a second edition of this classical work. The wealth of detail supplied on those points of technique which are necessary for the success of the experiments are likely to reduce to a minimum the chances of failure. Prof. Sherrington has made possible the application to classwork of an instructive and stimulating series of experiments which had been undertaken for the most part by experts and research workers. The second enlarged edition of the book has been compiled with the help of Dr. E. G. T. Liddell, who has worked with Prof. Sherrington for some years. It retains its original scope; the conduct of each experiment illustrating a physiological principle is given as an exercise, and each exercise is supplemented by a series of interesting and suggestive observations, including references. New exercises in this edition are those on the decerebrate knee-jerk, the inhibitory action of the cerebellar cortex, tetanus and immunity, and Prof. J. Mellanby's method of preparing secretin has been given in the exercise illustrating its action. The diagrams of apparatus and dissections are admirable.

THREE PLAYS:

The Switchback; The Pardoner's Tale; The Sunlit Sonata. By JAMES BRIDIE. London: Constable and Co., Ltd. 1930. Pp. 156. 7*s.* 6*d.*

HERE we have three plays, called respectively a comedy, a morality, and a farce-morality, bound in one volume. "The Pardoner's Tale" is, of course, an adaptation from Chaucer. The scene is laid in Scotland, in the eighteenth century, the characters being described as "three second-rate bucks," and the narration of the three murders which ends their carousals is a clever performance, which, however, seems to us to fail, despite the author's intention, to give an impression of utter horror. This macabre piece has not been staged, but "The Sunlit Sonata" has been played by the Scottish National Players in Glasgow. This is a bitter and brilliant indictment of many attitudes, convictions, and persons, and if the farcical side overshadows the moral side, probably this has been the writer's design. From the accurate description of the characters, especially where the Deadly Sins are introduced in appropriate costume, he will have drawn his inspiration for the dialogue. The outstanding feature in these two pieces is their originality, but in "The Switchback" we have really subtle character drawing, humour, and sense of drama. It is this play, which was produced last year at the Birmingham Repertory theatre, which has brought the volume to our notice, for here the medical situations supply the main arguments in this story. That story is neither very nice nor very probable, but the various characters tell it with force and humour, though the main exponent of the comic side of things as they occur fails occasionally to be comic when her attempts are most vigorous. Medical men familiar with the muddle in which the novelist or dramatist generally finds himself when dealing with professional problems will not be surprised to learn, on the evidence of this play, that the author is a doctor who is writing under a pseudonym.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 15, 1930.

DIET AND THE TEETH.

FOR the last 12 years Mrs. MAY MELLANBY has devoted herself to a study of the effect of various kinds of diet on the development and structure of the teeth, and especially upon their liability to disease. This work, begun at the field laboratories in Cambridge, has been continued since 1921 at the University Field Laboratory in Sheffield, which was equipped by a donation of £1000 from local insurance funds—an example of imaginative expenditure on the part of panel practitioners whose reward has been immediate. Throughout this time Mrs. MELLANBY has published a number of papers dealing with various aspects of this field research, and has succeeded in producing convincing evidence that the teeth are peculiarly sensitive to the presence (or absence) in the diet of specific food factors which determine not only the perfection of dental structure, but also the resistance to influences which initiate decay. Every step in her argument has been taken after exhaustive investigation, and the protocols of her experiments, as far as they deal with the structure of teeth in dogs, are now issued, in a lavishly illustrated report, by the Medical Research Council.[1] Fortunately the results lend themselves to summary.

The development in dogs of perfect teeth, Mrs. MELLANBY writes, can be ensured by an adequate supply of vitamin D, either as found in natural foods—e.g., egg-yolk, milk, suet, cod-liver oil—or as artificially produced in foods by irradiation of their ergosterol content or even by irradiation of the animal's skin. Proteins, carbohydrates, and most vegetable fats and foods such as cereals, oranges, and egg-white have no calcifying powers. Lard and bacon fat are usually deficient in vitamin D but vary, probably with the diet of the animal from which they are obtained. If the diet of a puppy is changed from one poor in fat-soluble vitamins to one rich in these substances there is an immediate response shown by improved calcification. When the process is reversed the response is delayed for a comparatively long period. An increase in the cereal intake has a deleterious effect on calcification apart altogether from its effect on the rate of growth. This effect is only marked when there is a certain deficiency of vitamin D, and it can be entirely overcome by a sufficiency of this vitamin in the diet. Cereals differ greatly in their anticalcifying effect on the teeth. Of those tested, oatmeal had the most effect, white flour the least; intermediate between these came maize (next to oatmeal), then barley, rye, whole-meal flour, and rice (polished and unpolished), the last corresponding closely to white flour. Wheat and maize germs were also found to have a deleterious effect on calcification. Mrs. MELLANBY has failed to associate the anticalcifying effect of cereals with any one known constituent of food such as (1) the absolute or relative amounts of calcium and phosphorus, or (2) the carbohydrate, fat, or protein, or (3) the acid-base ratio of the mineral substances. Her evidence suggests that there is a chemical entity of unknown composition in cereals, and especially in oatmeal and wheat germ, which actively interferes with the normal development of the teeth. Further, for the production of perfect teeth the diet must contain some calcium and phosphorus. If the diet is rich in vitamin D the amount necessary to produce such teeth may be very small; if the vitamin intake is very low, then extra calcium may effect some improvement in the structures. When butter is the source of calcifying vitamin in the diet, the calcium intake assumes a still more important rôle; without vitamin D perfect calcification will not take place however much calcium and phosphorus is given in the diet. She therefore deprecates the use of the expression "optimum amount" of calcium. Exercise plays little or no part in the development of the teeth in dogs. Exposure to sunlight, however, may result in the formation of good teeth with diets which would otherwise produce somewhat defectively calcified teeth. Proper maternal feeding is of great importance in the production of good teeth in the developing offspring; poorly calcified deciduous teeth can be produced in the litter by feeding the mother on a diet deficient in vitamin D. Nevertheless the defects so produced are less marked than those found in the permanent teeth when the puppy itself is fed on the same diet, owing no doubt to the sacrifice by the maternal organism of her own store of essential substances.

These are the conclusions drawn from the study of dogs at the Sheffield Field Laboratory. They relate only to dogs, but if, Mrs. MELLANBY adds, the experiments described have any significance for the human subject, it would seem likely that the ordinary diet, especially of the poorer classes, in this country will tend to produce imperfect teeth, since vitamin D is either absent from or deficient in bread, rice, oatmeal, barley, sugar, fruits, jam, most vegetables, lean meat of various descriptions, and white fish, articles of diet which form the bulk of the food eaten. The justice of this reasoning from dog to man has been repeatedly challenged by those who hold the view that oral hygiene is the secret of the prevention of dental decay, and that the interaction of food and bacteria in the mouth is the most important factor determining the decay of teeth, but the results considered as a whole fall into line exactly with those obtained by Prof. E. MELLANBY in his work on the calcification of bone in young animals. The remaining parts of the report which are yet to come will deal with the application to the teeth of other animals, including man, of the principles established in the case of the dog. The arena will then be set out for a clash of arms on one of the most vital socio-medical problems of our time. Meanwhile everyone must be grateful to Mrs. MELLANBY for so clear a presentation of a complicated problem.

◆

WHEN CONDUCT IS INFAMOUS.

WHEN dismissing an appeal a few weeks ago Lord Justice SCRUTTON remarked that it was a pity that the words "infamous conduct" occurred in Section 29 of the Medical Act of 1858 as a ground for removing a practitioner's name from the Medical Register. What the statute meant, said Lord Justice SCRUTTON, was serious misconduct in a professional respect—that is to say, viewed in the light of the rules governing the profession. Towards some such paraphrase, indeed, there has been a demonstrable tendency in recent years. The apothecaries, in their Act of 1874, copied the "infamous conduct" of the Medical Act, but in 1878 the Dentists Act significantly expanded the phrase to "infamous *or disgraceful* conduct in a professional respect." Soon afterwards the Veterinary Surgeons Act dropped the "infamous" and was content with the epithet "disgraceful." The present Architects (Registration) Bill, still awaiting its chance of becoming law, follows the veterinary surgeons' precedent with "any conduct disgraceful to him in a professional respect." This slightly modifies the similar Bill of 1927, which proposed to remove an architect's name from the register on conviction for felony or misdemeanour or on his being judged by the discipline committee after due inquiry to have "conducted himself in a manner derogatory to his professional character." The Engineers Bill a few years ago spoke of "conviction of any henious offence" and "unprofessional conduct of a serious nature." These examples show the tendency to approximate to such language as Lord Justice SCRUTTON has used and to abandon the obsolete implications of infamy.

---

[1] Diet and the Teeth: an Experimental Study. Part I.: Dental Structure in Dogs. By May Mellanby. Medical Research Council, Special Report Series. No. 140. H.M. Stationery Office. 1929. 17*s*. 6*d*.

What, after all, is infamous conduct? The history of past centuries gives the answer. Certain crimes were technically infamous—treason, forgery, perjury, and all offences involving the charge of falsehood. Conviction for these crimes disabled a man from being a witness or a juror. A man who thus became infamous was not merely discredited as a witness; he could not give evidence at all, though a pardon could restore his credit and capacity again. Research into these matters takes us back to the Middle Ages. Conviction and judgment in cases of barratry and præmunire, we are told, also led to infamy. In addition conduct might be infamous if it caused a man to be put in the pillory or whipped. Technical distinctions were subtle. At common law the pillory meant infamy, but the civil or canon law took no account of the pillory unless the offence itself was infamous, so that a man could be a good witness to a will in an ecclesiastical court provided that the conduct for which he was pilloried was not infamous according to ecclesiastical ideas. Moreover, if the accused could claim benefit of clergy, accompanied by burning in the hand under the statute of 18 Elizabeth, he escaped the disability of infamy. These anachronisms disappeared about a century ago. Benefit of clergy was abolished in 1827; the pillory was abolished for all offences except perjury in 1816 and for perjury itself in 1837. In 1828 punishment for felony, once it had been endured, was given the effect of a pardon under the great seal, and punishment for any misdemeanour except perjury, once endured, ceased to render a man an incompetent witness; these two provisions almost put an end to infamy. Finally, in 1843, Parliament formally enacted that crime should no longer incapacitate anyone from giving evidence.

These historical details reveal the language of Section 29 of the Medical Act to be some 100 years out of date. Infamous conduct—the conduct that involves infamy—has now no legal significance; its popular meaning is elastic; its interpretation is invidious. To modernise the language by a direct ad hoc amendment of the Medical Act (to give effect to Lord Justice SCRUTTON's paraphrase) might stir up unprofitable controversies. A rewriting of the Medical Acts in consolidated form (a process now being applied to the Solicitors Acts) would offer a better opportunity. Meanwhile it may be remembered that, although "infamous conduct" was inserted in Section 29 in the public interest, it does not fall to the public to interpret the words. Medical practitioners are not in serious doubt as to the conduct to which the words refer, for everyone whose name is placed upon the Register knows what is expected of him.

DIABETES IN CHILDHOOD.

BEFORE insulin came into use juvenile diabetes was universally regarded as a hopeless disease, in which no line of treatment could do more than postpone for a year or two the onset of coma. E. P. JOSLIN, who had treated 169 children between 1914 and 1922, found only one-third of this number alive at the end of the period. The statistics of the Mayo Clinic illustrate how completely insulin has altered the prognosis, for out of 164 cases treated in the clinic since 1923, 147 were alive in 1928. Nevertheless, a case mortality as low as even 10 per cent. in such a series leaves room for improvement, and F. N. ALLAN and R. M. WILDER,[1] in analysing these statistics, have ascertained as far as possible the cause of death in each of the remaining 17 cases. Their findings are instructive. Most of the patients came to the clinic from a distance, afterwards returning to their own medical attendants, and only one of them, a child admitted moribund in diabetic coma, died actually in the clinic. In eight of the remainder insulin either was not used or was suspended owing to ignorance or prejudice on the part of the relatives or doctor; and in four more the disease was allowed to get out of control. Two patients died of intercurrent infectious diseases (encephalitis and influenza), one child proved resistant to insulin, even in large doses, and in the remaining case coma was not recognised at first (owing to defective Benedict's solution), and fatal hypoglycæmia followed the use of too heroic doses of insulin. It is evident from these figures that in the future, as prejudice is overcome and the value of insulin becomes universally recognised, the immediate mortality in juvenile diabetes should be limited to those rare cases in which insulin, even in enormous doses, has no effect on the blood-sugar. Whether insulin will have any effect in reducing the incidence of later complications, such as gangrene and cataract, time alone can show. Meanwhile the lesson furnished by the Rochester statistics should be learnt. Every diabetic child should be treated with insulin and should be regarded as a potentially severe case, even if the response to treatment is immediate. A diet adequate in caloric requirements and containing sufficient protein, accessory food factors, and minerals to allow normal growth, is of course necessary, and the balance between diet and insulin must be varied from time to time as circumstances demand. Ketosis and the conditions which favour its appearance must be watched for vigilantly and treated promptly and thoroughly. Many lives would be saved if it were more widely known that abdominal pain and vomiting are amongst the commonest and earliest symptoms which usher in diabetic coma. If the diagnosis of coma is delayed until the patient is unconscious the most energetic treatment may not infrequently fail to save life. An infectious illness in the diabetic child should never be treated lightly. Not only is the carbohydrate tolerance depressed in many cases by the toxæmia, but the child loses its appetite and is prone to develop a starvation ketosis which very easily merges into diabetic coma. Confronted by such circumstances many practitioners, fearing hypoglycæmia, reduce or suspend the insulin; but if coma is to be avoided the need for insulin is never more imperative than at these crises. Most physicians will agree with F. N. ALLAN's statement that "the need for insulin during sickness, even when no food is taken, is something that everyone should know." *It is, however, inexcusable to allow any diabetic patient to starve during an intercurrent illness.* The glucose equivalent of the diet can, and should always, be given in some easily digested form such as sugar, orange-juice, or milk. The insulin can then be increased if necessary, and the risk of hypoglycæmia and starvation ketosis can be ignored.

Annotations.

"Ne quid nimis."

WILLIAM ERNEST HEMPSON.

THE death of Mr. William Ernest Hempson, who as solicitor to the Medical Defence Union and later to the British Medical Association was brought for nearly forty years into close association with the medical profession, will be learned with regret by a large number of our readers. He was a Suffolk man, and received his education at Ipswich Grammar School before admission as a solicitor in 1880. He made a fortunate start in his calling by early association with the well-known firm of Freshfields, but some forty years ago he made an independent start and founded the firm now represented by Messrs. Oswald Hempson and Colin Oliver, of which he was senior partner at the time of his death. The number of difficult and delicate situations which were placed before Hempson was very large during his long period of official work, and it was generally admitted that his advice was sound, while his intimate acquaintance with regrettable circumstances involving doctors brought with it no cynicism, but only a keen desire to alter the professional factors which seemed at fault. In 1928 he relinquished the personal appointment of solicitor to the British Medical Association, and his firm was appointed in his place, while in recognition of his many years of work he was elected an honorary member of the Association. He served our calling well, and while the public nature of his duties secured him high respect, there are many individual doctors who will mourn his loss as a friend to whom they had reason to be grateful.

PERFORATING INJURIES OF THE EYEBALL.

IN his Hunterian lecture delivered before the Royal College of Surgeons of England on Feb. 5th, Prof. J. Herbert Fisher strongly advocated the removal of magnetisable foreign bodies from the eyeball by the scleral route, in preference to the more recent method of drawing them into the anterior chamber by means of a giant magnet. With the latter procedure there is considerable risk to both the ciliary body and the lens of injury inflicted by the foreign body during its passage from behind forwards, and, as is well known to ophthalmic surgeons, the ultimate results to vision, when this method is adopted, are not good in the majority of cases. On the other hand, there are two sources of danger which have prevented many surgeons from adopting the method of scleral incision. One is the danger of sepsis, and the other the danger of detached retina which is liable to follow any considerable loss of vitreous. With regard to sepsis, Prof. Fisher pointed out a possible source of infection that is apt to be overlooked. Even where the lacrymal sac has been successfully removed and it is believed that any possible danger of pneumococcic infection from a lacrymal mucocele has been averted, it is still possible for pneumococci to lie hidden in the canaliculi, unless these channels have been cauterised. In one case in which the pathologist had reported the ocular conjunctiva bacteria-free, this had happened with disastrous results. Therefore Prof. Fisher emphasised the wisdom of always completing the operation of excision of the sac by cauterisation of the canaliculi. With regard to the danger of vitreous loss, Prof. Fisher advises insertion of sutures on each side of the line where it is proposed to make the scleral incision before the actual incision is made, so that after the extraction of the foreign body the wound may be closed with the least possible delay. With this precaution the amount of vitreous lost will in all probability be small and even if a limited detachment of the retina does ensue the prognosis is good, contrasting strongly with the bad prognosis inherent to cases of detachment occurring in eyes previously diseased or myopic. Two cases were cited illustrating this point, where reattachment of the retina took place within a comparatively short time, and full vision was retained. A caution was uttered by Prof. Fisher on the necessity of correct interpretation of the X ray skiagrams which are taken with the object of localising the exact position of a foreign body within the eyeball. At one time, even at Moorfields, charts were in use from which it was possible to draw fallacious conclusions in some cases as to whether a foreign body was within or without the scleral coat, and an instance was given in which, if the old chart had been relied on, it would have been concluded that a foreign particle was situated within the eyeball, whereas it was actually lying on the external surface of the sclera whence it was removed without any difficulty. Prof. Fisher further contrasted the sequel of particles of glass remaining within the eyeball, which may be harmless except so far as their mechanical effects go, with the inevitable effects of iron particles causing siderosis and the still more disastrous result of retained particles of copper which lead inexorably to the destruction of the eye. Finally, he referred to the phenomenon of cystic formations of the iris or anterior chamber sometimes caused by perforating wounds which involve the corneal epithelium in their track.

THE TEACHING OF PREVENTIVE MEDICINE.

IT has been said that the medical profession, like the phœnix, is destined to destroy itself in a fire of its own building: its culminating achievement will be the abolition of disease, and with it the practice of medicine as a means of livelihood. Although this magnificent end is still remote, there is nowadays a steady supply of contributions to the funeral pyre, and in this category we may place a book[1] lately received from the United States. At Harvard University it was felt, we are told, that the regular course in preventive medicine was bound by the limited time available to confine itself to the question of the protection of the community as a whole, and that little was taught concerning the protection of the individual. The same probably applies with equal force to the teaching at most English Universities. The student's curriculum—the diminutive is hardly appropriate at the present time—was considered already sufficiently full to make a further addition undesirable. For the last four years the policy has therefore been adopted of inspiring the teaching throughout the course with the spirit of preventive medicine. In this way not only are glimpses given from the first of the way in which the material can eventually be applied in practice, and so the teaching is made more interesting, but also throughout his whole training the student is imbued with the idea of the prevention of disease. Each section is written by the teacher of a particular subject, and sets out the points in prophylaxis that can appropriately be introduced into the lectures. For example, while teaching the anatomy of the perineal muscles one could stress the importance of their proper repair after birth injuries, and the results that may follow neglect. In a volume of small size it is clearly impossible, nor is it intended, to enter in detail into the technique of the measures that are mentioned. The essential object is to put forward the underlying principle, and to illustrate the way in which it may be carried out in the ordinary way of teaching. Twenty special subjects are dealt with—an indication in itself of how subdivided the curriculum has become. The sections devoted to medicine and bacteriology are naturally the longest, for these subjects are most rich in opportunity for the indication of prophylactic measures. The section of surgery includes subdivisions dealing with types of anæsthetic, and points in the pre-operative preparation of patients. The book is definitely written as an experiment, and this, the first edition, is interleaved with blank pages for the insertion of additions and suggestions. The subject matter is very comprehensive and in every way concise and informative, so that practitioners will find much of interest; but in particular it should be read by all who are interested in the teaching of students, because of the original point of view and principle that underlies its production. In these days of specialisation, subjects tend to become multiplied, and teaching consequently becomes divided into separate compartments. Those who instruct in special subjects are naturally absorbed in them, and so are apt to lose sight of the relationship of their specialty to the practice of medicine as a whole. This book marks a definite step in the opposite direction, and an attempt to remedy the defects in the medical curriculum produced by over-specialisation.

[1] Synopsis of the Practice of Preventive Medicine. Harvard University Press.

THE ADAPTIVE BEHAVIOUR OF BODO.

It is well known that races of bacteria more than usually resistant to a disinfectant may be obtained by cultivating them in dilute solutions of the poisonous substance; that the heat resistance of a bacterium may be increased by breeding from those which survive a heating which kills the majority; that a dose of an arsenical given to a mouse infected with trypansomes may lead to the appearance of a race of parasite which is immune to the drug; and that organisms of the typhoid-*coli* group may "learn" to ferment dulcite or lactose by continually growing in the presence of these substances. The fact of the occurrence of these resistant races, and the facile rapidity with which they may arise are, of course, of the highest practical moment. They would also be of great importance in general biological theory if their interpretation were more certain than it is. On their face value the phenomena look like examples of the direct purposive adaptation which so many biologists have believed in, but which has been so difficult to prove, at any rate to the satisfaction of those whose mental temperament is adverse to such an explanation. And it has always been just possible that they illustrate nothing more than progressive selection. Among the enormous numbers of which an ordinary bacterial population is composed, extreme variants may be expected to occur, and if an ordinary broth culture of the typhoid bacillus included one individual which could eat dulcite it is easy to believe that it would be impossible to make its presence manifest until it and its descendants had been differentially encouraged by a suitable medium. The "arsenic-fast" strains of trypanosomes may well arise in the same way. But it is more difficult to accept this way of looking at the results of the experiments with disinfectants, and especially those with heat; the possibility of growth after a certain amount of heating may be taken to indicate the heat resistance of the most resistant individual of the original strain, and any considerable increase of resistance in the descendants of these survivors is not easy to explain by simple selection. Both technically and theoretically, however, the subject is full of difficulties, and we welcome the contribution to it made by Dr. Muriel Robertson in the last number of *Parasitology* (vol. xxi., p. 375), in her study of the reaction of a free-living flagellate protozoon, called Bodo, to acriflavine. Bodo multiplies by simple fission, and its life-history is not complicated by conjugation or anything like a sexual process: systematically it is related to the trypanosomes. It grows well in pure culture on artificial media, and normal strains occasionally just survive in a concentration of acriflavine as high as 1/5000, though their resistance is usually less. By the progressive subcultivation of the survivors in such experiments, a strain has been obtained which will grow well and continuously in 1/1500 acriflavine, though it cannot survive in 1/1000. If such a resistant strain is cultivated on normal media containing no acriflavine its resistance falls slightly and slowly; it remains far above the normal level for at any rate many months. It seems clear that a heritable modification has been impressed upon the animal, and that the modification is in respect of the feature in the environment which has caused it. Since abundant cultures of bodo can be obtained without much difficulty from single individuals, it is hardly possible to believe that the resistance finally achieved was already present even in one of the original untreated population, with which many concordant experiments were made. Dr. Robertson points out, too, that a culture in a concentration on the border of the lethal limit cannot, as a rule, be subcultivated into the same concentration in the early days of the experiment, while it can be continued into the drug at a later period in the evolution of the survivors. Such a result is unintelligible on the hypothesis of simple selection; it is completely in harmony with the idea of progressive adaptation with which Dr. Robertson herself is in sympathy—as she may well be in Lamarck's centenary year. Acriflavine produces also a curious morphological change in bodo, which in the presence of the drug loses the chromatinic granule at the base of the flagella, known as the parabasal body. This occurs in a proportion of the population (never more than about three-quarters), which depends on the concentration of acriflavine and the resistance of the strain of bodo; a concentration of the drug which produces the maximal number of aparabasal individuals in a normal strain produces hardly any in a resistant strain. The proportion of altered bodo is therefore an anatomical measure of resistance to acriflavine. Arsenic-fast trypanosomes are changed in the same way, which affords an elegant control on the survival experiments to which alone bacteria can be subjected.

MORPHINE AND RENAL FUNCTION.

It has long been taught that morphine should be used with caution in nephritis, and Burney Yeo, speaking of its value in controlling uræmic convulsions, advised sparing administration, lest "the restlessness of uræmia be relieved by the repose of death." The work of Sisk and Beyer, however, went to show that in therapeutic doses morphine has no deleterious effect on the kidney, and R. S. Ackerly,[1] who quotes them, is able to support this opinion from experience of 177 cases of acute and chronic morphia poisoning. In three of these, he says, there were signs and symptoms of nephritis, with abnormal urinary constituents. The remaining 174, who had no symptoms, included 21 with some abnormal constituent in the urine. Of these, four showed albumin, casts, and red blood-cells; 11 albumin and casts; two albumin and red blood-cells; three a trace of albumin only; and one red and white blood-cells. None of these patients had a high blood pressure or œdema. Eleven of them showed some other condition besides morphine poisoning: two were heavy drinkers, one had a stone in the kidney, four had glycosuria, two syphilis, one gonorrhœa, and one optic neuritis with petechial hæmorrhages into the skin. In no case could it be said with certainty that the presence of abnormal urinary constituents was due to morphine, and in all of them the amount of morphine taken was greatly in excess of therapeutic doses. Ackerly advises that "morphine should therefore be used whenever indicated without fear of renal complications secondary to its use." The experiments of Haines and Milliken in 1925, he says, showed that renal function is improved by morphine and atropine in the usual doses, and that morphine given with ether prevents the inhibition of function produced by ether alone.

STATE BACTERIOLOGY IN CZECHO-SLOVAKIA

SCIENTIFIC work suffered a severe setback in Central Europe during the late war, and in Czecho-Slovakia one of the first tasks of the new Republic was to establish a State Institute of Hygiene, to be associated with the University of Prague. In 1920 the Rockefeller Foundation offered assistance and advice, and plans for the new buildings were prepared; the late Prof. Pavel Kucera became the first Director. The work was to include the production of sera and vaccines, which had hitherto always been imported, and in 1923, though the buildings designed for this section were still incomplete, it was decided that a provisional department should begin work in some laboratories lent by the Institute of Pathology of the University. The experimental animals were quartered in some old farm buildings on the site of the new Institute. During the next two years the members of this section began to prepare vaccines, to form reserves, and to instruct municipal workers. In the autumn of 1925 the new buildings being complete, the department was transferred to them, and the final stages of production—filtering and packing—were begun. Eight months later the first products were on the market, and by the end of 1926 the department was fully established. Since 1927 the activities of the department have proceeded according to plan, and we learn from the first number of its journal[1] they have included the manufacture and distribution of sera and vaccines, and the publication of propaganda on prophylaxis by vaccines and serum immunisation. The demand for the products of the Institute has steadily increased, and additions to the staff have been found necessary to meet it, so that from four workers in 1923 the number has now grown to 42. In spite of the continual claims of routine work, time has been found for research, and one part of the staff is engaged in trying to solve such practical problems in serology as are presented to them. The Institute consists of a two-storied building, designed to keep aseptic and infective work entirely separate; it is equipped with suitable cold-chambers and sterilisers of modern design, and all noisy apparatus is installed in the basement. The laboratories are excellent, and the building is of a size sufficient for the work undertaken, but without useless space. Special "boxes" made of iron, with glass windows, and supplied with filtered air, are used for important work such as the production of vaccines and the inoculation of cultures. The farm is 30 kilometres from the Institute, among wooded surroundings; the delays resulting from this isolation are reduced as much as possible by means of the telephone and motor-car, and the excellent health of the animals is thought to counterbalance other disadvantages. The quarters at the farm are kept clean and well ventilated, and the horses can be turned out to grass when necessary. The staff, including a veterinary surgeon, are accommodated on the premises. Preparation of doses of antigen is performed on the farm in a special laboratory, and a chamber is reserved for injections which are carried out by means of an electric pump. Sterilisation of the finished sera is followed by experiments to test their strength, and by standardisation; in the case of antidiphtheritic and antitetanic serum international units are employed. Tests of sterility are made before and after filling bottles or ampoules, and a written report of all tests is submitted to the chief of the section, who adds his signature to this report only when he has examined it personally. No product is packed until this signature has been added. The sera and vaccines prepared are all those in common use, such as antidiphtheritic, antitetanic, antistreptococcic, antimeningococcic and normal sera, and, among the vaccines, T.A.B., the toxin of the scarlatinal streptococcus and others. The extension of the work will depend on the sales; it has been mentioned that before 1926 all these products were imported, and there is still no duty on foreign sera and vaccines. The members of the Institute have no wish that this should be altered, since they feel it essential that medical men should choose those products they believe to be most efficacious without constraint. A more gradual evolution, moreover, will better suit the convenience of the section at present than a sudden great increase in demand. That the sales of the products of the Institute are rising steadily is shown by the increase in orders noted since 1926.

Since the opening of the section in 1926, propaganda has been distributed widely; all medical men have received copies of price lists, accompanied by brochures explaining the use and value of sero- and vaccino-therapy. Articles on the subject have also appeared in the medical journals, and conferences have been arranged. With the expedition of the work of production it is hoped that further opportunities for research will be given to the staff of the Institute during the coming years.

PROF. BRAILSFORD ROBERTSON AND HIS WORK FOR ANIMAL NUTRITION.

ALONG with the news of his death from pneumonia at the age of 45 comes a copy of a report by Prof. Brailsford Robertson of Adelaide on the work for the past year of the division of animal nutrition of the council for scientific and industrial research of the Commonwealth of Australia. He was a singularly gifted man and one of the liveliest biochemists of his time, widely known outside his immediate circle for his autocatalytic theory of growth which, if it did not meet with universal acceptance in its simplest form, did better for the progress of knowledge by stimulating observation, experiment, and thought on the subject. He was an Adelaide graduate and after 15 years at the universities of California and Toronto he came back as professor of physiology and biochemistry, and everywhere he leaves behind him a trail of students roused by his vivid personality and his enthusiastic imagination. The last few years he had been busy developing research work on sheep and how they live and grow, and this last report gives a most interesting account of the various inquiries which are in hand, especially in connexion with the growth of wool. Horns, hoofs, hair, and wool are largely composed of peculiar proteins which contain a large proportion of the sulphur-containing amino-acid cystine. Animals cannot synthesise cystine, hence the weight of a sheep's fleece may likely be limited by a deficiency of this necessary substance. Ordinary fodder protein contains about 1 per cent. against 13 per cent. in wool. Search has therefore been made for some *available source of protein which is rich in cystine*. Fibrin contains a good deal and meal made from dried blood is possibly useful; yeast also has about 4 per cent. The richest extraneous source, however, seems to be the juices of plants of the rubber-producing trees of the Ficus group and the liquid left after the coagulation and separation of the rubber contains great quantities of cystine, and might in one way or another be made useful. Finally, Prof. Robertson and his colleagues have explored the possibility of rendering the cystine present in the hair, horns, and hoofs of slaughter-house refuse digestible and capable of assimilation by hydrolysing the crude materials with hydrochloric acid, and have obtained promising results with this preparation in field trials.

---

[1] Les Travaux de l'Institut d'Hygiène Publique de l'État de Tchécoslovaque, January, 1930.

It is the same idea as was developed by N. Zuntz in Germany during the war to get the maximum yield of wool from the sheep; it was successful at any rate to the point of making one of his co-workers shave twice a day instead of once, and a few years ago a proprietary preparation of hydrolysed keratin was widely advertised for human use. It is indeed evident that what does for sheep will probably do for man, and embarrassed rubber companies may well appear on the hair-restorer market. Other topics of less immediate human interest are the deficiency of phosphates which, as in other countries, is widespread in the soils of Australia, and the demonstration that iodine is present in plenty. The whole report is an admirable example of what can be done by the real biochemist (biologist as well as chemist) and the reading of it can only accentuate our sense of the gap which will be left by the loss of Prof. Robertson at the height of his powers.

THE USE OF PERCAIN.

A NEWLY introduced local anæsthetic, percain,[1] bids fair to be a valuable adjunct to the agents available for producing local analgesia whether by surface application or by injection. Experience so far is too slight for dogmatic assertions, but it certainly warrants the belief that we have here an analgesic of exceptional power, and especially of a long lasting effect. Its superiority over novocain in this respect is maintained by several different observers who are working with it. Some have been using it mainly for the nasal mucous membrane, others for splanchnic and for paravertebral analgesia. All seem to agree on the remarkable duration of the analgesia produced. Experimentally percain has been shown to be about ten times as effective as cocaine. It is also slightly more toxic than this drug, but as it can be used effectively in such very weak concentration there appears to be no danger of toxic effects in practice. So far no reports of ill-effects have reached us, but of course it is too early yet to know whether addiction is to be feared as a consequence of its employment. Percain is sterilisable by heat. It has apparently a slight vasodilator effect, for which reason it is generally used, as is novocain, with small additions of adrenalin, except in situations where vasoconstriction has no special advantage—e.g., in splanchnic and spinal injections.

DELAYED NOTIFICATION OF TUBERCULOSIS.

IT is generally agreed that no public scheme for the treatment of tuberculosis can come into effective operation unless the cases of tuberculosis are reported to the local authority as soon as they come to the knowledge of the practitioner. In his last annual report, Sir George Newman remarks that such notification is becoming more effective year by year, although a proportion of health officers still complain that in a number of cases it is only at a late stage that the disease is first brought to their notice. Under Article V. of the Tuberculosis Regulations the onus is laid on the practitioner to report within 48 hours of becoming aware that any person he is attending is suffering from tuberculosis, unless he has reasonable ground for believing that the case has already been notified. Late notification is no doubt due as often to the delay on the part of the patient in obtaining medical advice as it is to the delay on the part of the practitioner in making and reporting his diagnosis. The Joint Council which acts as a liaison between the various tuberculosis groups has now issued a leaflet of advice on the subject through its hon. secretary at 123, Torquay-road, Paignton, Devon. Notification was introduced 18 years ago, and, while the Council agrees that a wide unofficial discretion has been for the best, it thinks the time has come to recommend practitioners to notify under the following circumstances:—

(1) When suggestive constitutional symptoms are present and sufficient corroborative evidence of tuberculosis is available.

(2) When tubercle bacilli have been found in the sputum or elsewhere.

(3) In cases of hæmoptysis or pleural effusion where other symptoms and signs point to the existence of tuberculosis.

(4) In acute general tuberculosis, and tuberculous meningitis.

(5) In persistent chronic adenitis, arthritis or bone disease, where causes other than tuberculosis can be reasonably excluded.

(6) In tuberculous dermatitis, and lupus vulgaris.

(7) In tuberculosis of the abdomen, of the genito-urinary tract, or of other organs.

In children it is agreed that catarrhal pulmonary infections frequently simulate tuberculous disease, making diagnosis difficult; in chronic adenitis also prolonged observation may be required to determine whether the infection is due to septic organisms or to tuberculosis. Most of the objections to notification arise, it is suggested, from lack of discretion in the visiting of patients, and from the occasional neglect to treat information about tuberculous patients as confidential. It should be made widely known that if the notifying doctor desires that no public health officer should visit the home of the patient, the wish is generally respected. If he does this the practitioner assumes responsibility for seeing that everything possible is being done to limit the spread of infection and to deal with the causation of his patient's breakdown. The practitioner can vitally assist prevention by:

(*a*) Securing the proper disposal of sputum. The easiest way of dealing with sputum or other infective discharge is by boiling or burning. If a cup is used, it should contain disinfectant, and have a non-perforated, removable, or hinged cover.

(*b*) Seeing that an infective patient has a bedroom to himself, or if this is impossible, a bed to himself, separated by at least five feet from any other bed, in a well-ventilated room, and

(*c*) Advising that an infective patient should not handle milk or other foodstuffs, or have the intimate care of young children.

The Council finally reminds the practitioner that the tuberculosis officer is always available for the diagnosis of difficult or doubtful cases, such as unexplained hæmoptysis and for suggestions as to treatment.

CHEMICAL SPERMICIDES.

CONSIDERING the number of spermicides on the market, their wide use, and the sociological consequences of their efficacy, it is indeed remarkable that nobody seems to have directly investigated their effects upon spermatozoa. There is a widespread feeling that existing contraceptive methods are in various ways impracticable by persons of low intelligence, and medical men are often embarrassed by questions from their patients as to which are the best methods. A paper appearing in the current *Journal of Hygiene* (Jan. 20th) will therefore be of widespread interest. Mr. J. R. Baker, D.Phil., has elaborated a technique for testing the comparative spermicidal power of different contraceptives on the market, and also of the various pure substances which constitute the active principles of these preparations. It is an in-vitro technique, and consequently does not reproduce perfectly the conditions of the human vagina, but these are imitated as closely as possible in the matter of temperature and acidity. Dr. Baker's conclusion is that quinine and chinosol, which are common constituents of pessaries, have a surprisingly small spermicidal power. A comparison of their efficacy with that of "semori" and "speton," two German foam-producing pessaries, has shown that one-tenth of a tablet of semori or speton is much more lethal to spermatozoa than is the whole of a quinine or chinosol tablet. Pessaries of quinine and chinosol, in a vehicle of cocoa butter, were found to be ineffective for as long as 12 hours after they had been dissolved and allowed to act upon guinea-pig sperm. That these pessaries have a contraceptive effect of some kind is strongly suggested, however, by a good deal of scattered clinical evidence, and Dr. Baker's work indicates that this effect is probably brought about by a mechanical action of the cocoa butter vehicle, rather than by the chemical action of quinine or chinosol. Further papers on the subject are to follow this one. The work was financed by the Birth Control Investigations Committee, and carried out in the Department of Zoology and Comparative Anatomy at Oxford.

A LONDON SUNLIGHT CLINIC.

THE Institute of Ray Therapy, opened at 152/154, Camden-road, N.W.1, provides treatment for sick and poor persons in London by ray therapy and kindred methods; it is also designed to be a training school for persons qualifying to administer such therapy, and a centre for research. The Institute, which is not allowed by its trust deed to make a profit, was founded with the help of an initial donation of £10,000, and fees will be charged to cover running expenses on the basis of a tariff drawn up with the help of the British Medical Association. Necessitous cases are treated free as well as members of the Hearts of Oak Benefit Society which reimburses the Institute for the treatment of its members. Persons whose income exceeds a stated limit will only be accepted at the special request of their own doctor when reasons are given. In any case the applicant must bring a medical certificate. Treatment is given between 2 and 9 P.M. each weekday by qualified nurses and a resident medical officer working under the direct supervision of Dr. William Beaumont, hon. medical director, who sees new patients (children) on Tuesday, 4 to 5 P.M., (women) on Wednesday, 5 to 7 P.M., and (men) on Thursday, 5 to 7 P.M. The equipment is strictly limited to various kinds of rays, neither massage nor any form of hydrotherapy being included; it is hoped to be able to assess the effect of such treatment in a wide series of disorders such as neurasthenia, rickets, septicæmia, surgical tuberculosis, delayed union of fractures, and various kinds of skin diseases, a list whose scope may be widened by the medical advisory committee which consists of Sir William Hale-White (president), Sir William Hamer (chairman), Prof. J. Eyre, Dr. Beaumont, Dr. P. P. Dalton, and Dr. J. Liddell, the two last being elected by the adjoining divisions of the British Medical Association. Dr. Eyre and Dr. Beaumont are arranging for research on the bacteriological and clinical sides, Dr. N. Lucas of the Lister Institute on the physical and pathological side. Courses of lectures will be given.

GIANT-CELLED SPLENOHEPATOMEGALY.

THE disease first described by Gaucher in 1882, which languished in the medical literature under the vague title of endothelioma of the spleen, has begun to attract more attention now that its ætiology is better understood. The idea of an inborn error of metabolism has been put forward, and biochemical investigations have been stimulated largely by recent descriptions of an allied disorder known as the Niemann-Pick disease. The latter is seen in young infants, and the signs are great enlargement of the abdomen, a curious bronzing of the skin, a raised cholesterol content of the blood, and increasing cachexia leading to death in the first or second year of life. Cells in the spleen, liver, lymphatic glands, and bone-marrow are found to be swollen and to contain lipoid material, as indicated by microscopical stains for fat, and similar cells have been seen in the lungs and thymus. On analysis the spleen contains a great excess of cholesterol and lecithin. This clinical condition can thus be contrasted with Gaucher's disease, which, though it often begins in early life, runs a much more chronic course. The spleen is much more enlarged than the liver, the cholesterol content of the blood is normal, and at necropsy the swollen cells are limited to the spleen, liver, lymphatic glands, and bone-marrow, and do not show the presence of a lipoid by any of the ordinary microscopical staining methods. Differentiation between the two disorders has, however, been made difficult by several recent descriptions of acute forms of Gaucher's disease which caused death in the early months of life. Thus Dr. Eugen Stransky,[1] of Vienna, has described a case where the differential diagnosis between the Gaucher and the Niemann-Pick type of disease was impossible on the evidence obtained. The child was the third in the family, and the two elder ones had succumbed in the first six months of life to an increasing cachexia and intercurrent infection. In the eldest an enlarged spleen and liver were reported at an inquest, while the second child was described as having Gaucher's disease. In Stransky's case death occurred from bronchopneumonia, and no autopsy was permitted. Clinical examination had shown a wasted baby with a curiously bronzed skin, an enlarged abdomen due to a large, hard liver and spleen. A blood count indicated a secondary anæmia, but no leucopenia; the Wassermann reaction was negative, and blood cholesterol normal. The child had head retraction and increased muscular rigidity, and it is interesting to note that nervous complications of the Niemann-Pick disorder have been described. Such a case could well be classed as either an example of the infantile type of Gaucher's disease or as an unusual variety of the Niemann-Pick syndrome. Stransky's point in describing it is to stress the great difficulty of differential diagnosis. It is possible that in Gaucher's disease the cells of the reticulo-endothelial system are swollen with some product of abnormal metabolism, just as they are swollen with cholesterol in the Niemann-Pick disease. Overlapping is likely if both are examples of metabolic errors in early life, and for this reason Stransky suggests that the term giant-celled splenohepatomegaly should be used for the whole group.

ORBITAL INJECTIONS OF ALCOHOL.

FOR some years a few surgeons have made use of orbital injection in certain cases of painful eyes with very little vision, where excision is inadvisable or impracticable, and Dr. L. Weekers,[2] the Belgian ophthalmologist, has recently called attention once more to its value. In painful eyes with only a trace of vision remaining he has injected as much as a cubic centimetre of 80 per cent. alcohol without any manifest injury to the remaining vision, but in cases retaining some useful degree of vision he has been far more cautious, using solutions from 5 to 40 per cent., according to circumstances, after a preliminary injection of 2 per cent. novocain. The usual strength employed is from 20 to 40 per cent., but it is not advisable to exceed this percentage lest the optic nerve should be affected, though this has never happened in his experience. A needle 3·5 cm. long is introduced through the conjunctiva on a level with the external canthus in order to reach the ciliary nerves at the back of the orbit, and if the technique is correct an immediate relief of pain is experienced. Though this may be only temporary, it is none the less valuable, since it may suffice to tide over the time when operative measures can be taken under the most favourable circumstances. Or it may be repeated in a few days or weeks, and sometimes the relief seems to have been permanent. The procedure has been employed for traumatic affections, severe corneal ulcers, herpetic and other painful affections of the cornea, and for iritis. The kind of case in which it may be expected to be most valuable is the acute secondary glaucoma due to cyclitis, where the surgeon is in doubt whether to use mydriatics or miotics, or where it is desirable at any rate to postpone operation though the pain is so excruciating as to be little influenced by hot fomentations and sedatives. In the experience of Dr. Weekers the good effect of the injections has often been immediate and lasting. When it has been otherwise the cause is generally to be attributed to insufficient strength of the alcohol, and there is no reason why the injection *should not be repeated. Besides the relief of pain,* the injection of alcohol into the orbit in cases of absolute glaucoma appears to have a direct influence in bringing down the tension, but apart from these effects its action on the disease itself appears to be nil. In practised hands, however, it can do no harm. There may be a temporary paresis of the external rectus muscle or a temporary œdema of the lids, and there may be temporary loss of sensation in the cornea, but no ill-effects that are permanent are to be anticipated. Its value to patients whose pain is almost unbearable and cannot be otherwise relieved is obvious.

---

[1] Jahrb. f. Kinderheilk., January, 1930, p. 204.

[2] Scalpel, Jan. 25th, p. 85.

UNDER the Chadwick Trust a prize and medal may be given once in five years to a medical officer of the Army, Navy, or Air Force whose work has specially assisted in promoting the health of the Service to which he is attached. This prize and medal have just been awarded to Surgeon-Captain Sheldon Francis Dudley, Professor of Pathology and Lecturer in Tropical Diseases at the Royal Naval College, Greenwich, in recognition of his epidemiological research.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Rear Admiral W. L. Martin is placed on the retd. list at own request.

Surg. Capt. W. W. Keir to be Surg. Rear Admiral.

The following appointments are made: Surg. Lt.-Comdrs. (D.) R. J. M. Andrews to *Defiance;* and S. E. Brown to *Tamar,* for R.N. Hospital, Hong-Kong. Surg. Lt. (D.) G. B. F. Reece to *Resource.*

ROYAL ARMY MEDICAL CORPS.

The undermentioned Majs. to be Lt.-Cols.: G. W. W. Ware, vice Lt.-Col. R. C. Wilson to retd. pay; and C. J. Wyatt, vice Lt.-Col. H. St. M. Carter, to half pay.

ROYAL AIR FORCE.

The undermentioned Flying Officers are promoted to the rank of Flight Lt.: B. B. Kennedy, J. Kemp, J. B. Murphy, R. F. MacLatchy, and J. J. Quinlan.

INDIAN MEDICAL SERVICE.

The *London Gazette* for Feb. 7th states that "Officers who are now serving on temporary commissions in the Indian Medical Service and have been gazetted to temporary rank are hereby granted substantive rank on their temporary commissions equivalent to and in substitution for the temporary rank so gazetted, except in the case of temporary rank granted to officers in consequence of their being called upon to perform the duties of a rank higher than their usbstantive rank."

Lts. (T.C.) to be Capts. (T.C.): B. M. Rao, S. K. Menon, A. Singh, and M. Chandra.

Lt.-Col. F. V. O. Beit retires.

DEATHS IN THE SERVICES.

Surgeon Rear Admiral Edgar Ralph Dimsey, D.S.O., who retired in 1920, died on Feb. 5th, aged 68, joined the Royal Navy as surgeon in 1883, and became staff surgeon in 1895. He served in the Benin Expedition of 1887, was mentioned in dispatches, received the D.S.O. and the general African medal with the Benin clasp.

Major-General Sebert Francis St. Davids Green, C.B., C.B.E., R.A.M.C., retd., a graduate of Durham and an old Bart.'s man, died on Feb. 5th, at the age of 62, in the Queen Alexandra's Hospital, Millbank. He joined the A.M.S. in 1894 and served in India. At the outbreak of the late war he went to France with the Rawal Pindi British General Hospital, and in 1915 was appointed to its command, subsequently taking the unit to Mesopotamia. In 1916 he was appointed A.D.M.S. of Amara and A.D.M. of the Base, M.E.F., being mentioned in dispatches four times and created C.B.E. From 1921 to 1924 he was D.D.M.S., Scottish Command, and from 1923, when he was promoted to major-general, to 1927, D.D.M.S., Western Command, India. For some months he was officiating D.M.S. in India, afterwards retiring. He was an hon. physician to the King and was made C.B. in 1925. General Green's wife predeceased him in 1927, and he leaves three sons and two daughters.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

LXIII.

THE CLINICAL SIGNIFICANCE OF THE BLOOD PHOSPHORUS.

PHOSPHORUS is found in the blood, not only in the inorganic state, but also in combination with a variety of organic radicles, and in its several forms this element enters into many widely different phases of metabolism. It is not generally realised that less than one-twelfth of the total phosphorus is present as inorganic phosphate. Moreover, the relationship between this fraction and the remaining organically combined phosphorus is so intimate that some knowledge of the latter is essential to the full understanding of phosphorus metabolism. Table I. shows the distribution of phosphorus (P.) in normal blood.

TABLE I.—*Distribution of Phosphorus in Normal Blood.*

—	Phosphorus content as mg. P. per 100 c.cm. in—		
	Whole blood.	Plasma.	Corpuscles.
1. Acid soluble:			
(*a*) Inorganic	3·0	3·0	3·0
(*b*) Organic (ester phosphorus) ..	23·0	0·3	53·0
2. Ether-alcohol soluble (Lipin P.)	12·0	7·0	18·0
Total	38·0	—	—

In addition, traces of phosphorus are present as nucleic acid, in the nuclei of the leucocytes. The nuclein phosphorus is consequently present in some quantity in leukæmia.

Inorganic phosphate.—In health the level of inorganic phosphate in the blood varies between 2·5 and 3·5 mg. P. per cent., the average value being 3·0 mg. After a meal the level falls towards the lower limit of normal, probably as the result of increased secretion of insulin. In children, in whom ossification is more active, higher readings are usual—namely, from 3–4 mg. per cent.—and blood obtained from the umbilical cord at birth may contain as much as 6 mg. per cent.

Acid-soluble organic phosphorus.—This group, which will be referred to as "ester phosphorus," includes a number of phosphoric esters, of which adenine nucleotide, phosphoglyceric acid, and an ester capable of reducing alkaline copper solution (possibly a hexose-phosphoric ester) have been identified. This fraction is confined almost entirely to the corpuscles, but definite traces are found in the plasma. The amount of ester phosphorus in unit volume of corpuscles is one of the most stable constants of normal blood—more stable, for example, even than the hydrogen-ion concentration. An enzyme, *phosphatase,* controls the synthesis of these organic esters from the inorganic phosphate.

The *alcohol-ether-soluble phosphorus* consists of a group of complex lipoids such as lecithin, kephalin, and sphingomyelin. The term "lecithin," commonly applied to this fraction of the blood phosphorus, is misleading; "lipin phosphorus" is more satisfactory. The lipin phosphorus is divided unevenly between plasma and corpuscles. The corpuscular lipin forms with other lipoids a film on the surface of the corpuscle and varies very little either in health or in disease. The plasma lipin, on the other hand, is much more variable and may undergo considerable fluctuations in disease.

Technical Considerations.

Most of the early work on blood phosphate must be accepted with caution, for it was not known before 1914 that the distribution of phosphorus changes when blood is allowed to stand. Once the corpuscles have been laked, the liberated organic esters are very rapidly hydrolysed by the plasma phosphatase and the concentration of inorganic phosphate rises rapidly. Even after precipitation of the protein (which inactivates the enzyme) the phosphate content of the acid filtrate rises appreciably if the solution is allowed to stand at room temperature. Table II. illustrates the extent of this change.

TABLE II.

Blood filtrate.	Inorganic phosphate in mg. per 100 c.cm.	
	At room temp. 16° to 18° C.	At 35° C.
0 hour after precipitation	4·89	4·89
5 hours „ „	5·06	—
24 „ „ „	5·62	6·50
48 „ „ „	5·82	7·10

On the other hand, if the blood is shaken unduly or exposed to air it loses CO_2 and becomes more alkaline; enzyme synthesis now occurs and the phosphate content falls. For this reason serum obtained by defibrination may contain appreciably less phosphate than plasma.

Collection of specimen.—The value of blood phosphorus reports therefore depends on the adoption of rigid technique, and the following precautions should be observed in collecting the specimen. The blood should be collected in a clean *dry* syringe, and transferred to a dry tube containing powdered potassium oxalate (0·015 g. for each 10 c.cm. of blood). The tube should be inverted several times (not shaken) to dissolve the oxalate, and stored on ice. Analysis should be commenced immediately. Heparin must not be used as the anticoagulant, since it contains phosphorus.

Analysis.—The estimation is based on the blue colour which develops when a solution of inorganic phosphate is added to molybdic acid, in the presence of a reducing agent, sodium sulphite, and hydroquinone. The organic extracts are oxidised by combustion with nitric and sulphuric acids into phosphoric acid, which is estimated by the same method. In capable hands the experimental error should not exceed 2 per cent.

Expression of results.—In the interests of uniformity results should be expressed as milligrammes of phosphorus per 100 c.cm. of whole blood or plasma. The use of symbols obsolete in this connexion, such as H_3Po_4 and P_2O_5, leads to much needless confusion.

Physiology.

Sources.—Phosphorus is ingested in the food as nucleoprotein (meat), phosphoprotein (milk), lecithin, &c., (egg yolk, liver), and as inorganic phosphate.

Absorption.—Normal absorption of phosphate from the intestine depends on the balance between the phosphate and calcium of the food, the reaction of the intestinal contents, and the antirachitic vitamin. The influence of these factors will be discussed later in connexion with rickets.

Excretion.—Phosphorus is excreted as phosphate in the urine and fæces.

Function.—Phosphorus enters into the following metabolic processes:—

1. *Carbohydrate metabolism.*—A marked fall in the blood phosphate, accompanied by diminished excretion of phosphate in the urine, follows the injection of insulin. The organic phosphorus remains unaltered, and the fate of the phosphate which, in company with glucose, disappears from circulation is still obscure. L. Harden and W. J. Young have demonstrated the importance of intermediate sugar-phosphate compounds (hexose phosphates) in the fermentation of glucose by yeast, and there can be no question that phosphate is in some way essential to the storage or utilisation of carbohydrate.

2. *Muscular contraction.*—Sugar-phosphate compounds also enter into the chemical changes which precede the contraction of muscle, but here again the nature of the changes is unsettled.

3. *Ossification and calcium metabolism.*—The process of ossification entails the deposition of insoluble calcium phosphate on a framework of osteoid tissue. According to R. Robison a phosphatase, which can be isolated from ossifying bone, is responsible for this process by hydrolysing the organic phosphorus esters and so causing a local concentration of PO_4 ions, which in contact with calcium form an insoluble precipitate of calcium phosphate. The metabolism of phosphorus is closely interwoven with that of calcium, and many of the observed fluctuations in the blood phosphate can be accounted secondary to disturbed calcium metabolism. In general it may be stated that the relationship between the calcium and phosphate ions of the blood is reciprocal; that is, a rise in the calcium leads to a fall in the phosphate and conversely a fall in the former to a rise in the latter. The injection of parathyroid hormone, for example, which increases the blood calcium at the expense of the calcium in the bones, causes a fall in the blood phosphate. This reciprocal relationship is only approximate, however, and breaks down when other factors, such as changes in the pH of the blood or in the absorption of phosphate, enter into the question. Thus in rickets, where the absorption of phosphate is deficient, both the phosphate and the calcium may be subnormal.

4. *Neutrality regulation.*—The nature of the relation between the hydrogen-ion concentration and the phosphate content of the blood involves several conflicting factors. In the first place, alkalosis, by furthering storage of calcium and hypocalcæmia, tends to raise the blood phosphate, while acidosis, by mobilising the stored calcium, has the opposite effect. Secondly, the activity of the plasma phosphatase varies with the reaction of the plasma. Acidosis encourages hydrolysis and a rise in the phosphate at the expense of the organic esters. Alkalosis, on the other hand, favours synthesis and so tends to depress the plasma phosphate. In experimental acidosis induced by ammonium chloride the organic phosphorus esters of the corpuscles are greatly depleted, while the inorganic phosphate rises at first but may fall below normal later. Thirdly, the kidney, by selective elimination of appropriate quantities of the acid and alkaline phosphates of sodium, assists in maintaining the reaction of the blood at a constant level. It is, therefore, impossible to predict the effect of acidosis or alkalosis on the blood phosphate. In practice, however, it is observed that in alkalosis the level is usually raised (up to 5 or 6 mg. per cent.), but in acidosis no constant findings are recorded.[1]

Variations in the Concentration of Inorganic Phosphate.

It will be realised from the foregoing remarks that changes in the concentration of inorganic phosphate in the blood are likely to be encountered in any disease in which one or more of the following factors are altered.

Absorption.—1. Calcium-phosphate ratio of the diet. 2. Reaction of intestinal contents. 3. Antirachitic vitamin.

Excretion.—Activity of the kidneys.

Utilisation and storage.—1. Ossification. 2. Activity of the parathyroid glands (and probably the thyroid

---

[1] The terms "alkalosis" and "acidosis" are here used in the exact sense suggested by J. R. Marrack in a previous article of this series (THE LANCET, 1929, ii., pp. 512, 569), and imply an increase or decrease in the plasma bicarbonate. By "ketosis" is meant the presence of acetone bodies in the urine.

The ten mice which were kept alive to study after-effects of the exposure to low oxygen pressure showed definite improvement soon after return to normal oxygen pressure, but six died during the next two months, three probably as the result of accidental exposure to low temperature during severe frost. The remaining four mice were alive ten months later, having apparently recovered completely.

Pathological changes produced by the prolonged breathing of oxygen at 10 per cent. pressure were studied in two mice which died during the experiment, and in nine which were killed for histological examination. The changes observed fully confirmed the conclusion from my previous observations[6] that the chief factor deciding the powers to withstand low oxygen pressure is the heart muscle; a definite sign of heart failure was congestion of the organs, particularly the liver.

The general conclusion from this experiment is that none of the mice maintained normal health after breathing oxygen at 10 per cent. pressure for five weeks; this pressure of oxygen exists at about 20,000 feet altitude. Adverse effects were loss of appetite, loss of weight, and general weakness due to cardiac failure. Nevertheless the resistance exhibited by some few of the animals was of no mean degree.

Experiment 2.—In this experiment the previous result was confirmed, but the main object was to determine whether breathing oxygen at about normal pressure, 20 per cent., for one hour every day would render the animals more resistant to the low oxygen pressure, 10 per cent., and enable them to tolerate this low oxygen tension for a longer period. In this way evidence might be obtained as to whether it is worth while for climbers to breathe oxygen at normal pressure for about an hour every day. There was some evidence in favour of this, but on the whole the advantage gained did not appear very great except perhaps for one or two of the animals.

Two sets of 36 male mice (16–30 g.) were obtained each from a different source—viz., from an Essex stock and from our own stock at the Medical Research Council's farm. Half of the Essex mice and half of the farm mice, that is, 36 in all, were placed in one chamber (gas capacity about 300 litres) and treated as described in the first experiment, being given two weeks to acclimatise gradually to low oxygen pressure, reaching about 10 per cent. on the fourteenth day; they were then exposed continuously to 10 per cent. of oxygen for about four weeks by which time they all revealed inability to maintain normal health. The other half of the Essex mice and of the farm mice were placed in another similar chamber and treated in the same manner, except that they breathed oxygen at 20 per cent. for about an hour every day throughout the whole experiment, and thus had some daily "relief" from the low oxygen pressure.

Both chambers were arranged in exactly the same manner as regards position of cages, soda lime, oxygen supply, and large stirrers for mixing thoroughly the gas within the chamber. The two stirrers were propelled by one motor at a pace sufficient to mix the gas thoroughly in the chambers. The cages were made of fine wire mesh, and each contained six mice. Four small pots with food served for protection, behind each of which two mice could shelter from the moving air if they so desired. The temperature within the chambers varied between 16° to 20° C., fluctuating with that of the room in which the chambers were placed. Soda lime was spread out in dishes at the sides of the chambers and the carbon dioxide in the gas mixture did not exceed 0·20 per cent.

Great care was taken to keep the oxygen pressure similar in the two chambers, analyses of the gas being carried out at least twice a day. During the course of this experiment the barometric changes of the outside air were often sudden and marked, so that the chambers required more attention than usual. The oxygen pressure within the chambers was lowered by passing through them a mixture of oxygen (7–10 per cent.) and nitrogen, both chambers being treated in the same manner. To raise the pressure to 20 per cent. for one hour in the "relief" chamber, this chamber was not opened to the air, but the required amount of pure oxygen was passed through it. The other chamber, termed for brevity "no relief," was ventilated in a similar manner to the "relief" chamber, but with a gas mixture containing oxygen at 10 per cent. pressure.

During the two weeks of acclimatisation the average oxygen pressures within the chambers were 16·0 per cent. and 13·0 per cent. for the "no relief" chamber and 16·4 per cent. and 13·8 per cent. for the "relief" chamber, excluding, of course, the one hour's daily "relief." During the last four weeks of the experiment the average weekly compositions for oxygen were 11·3, 10·0, 10·2, and 10·7 for the "no relief" chamber, and 12·0, 9·9, 9·9, and 9·9 for the "relief" chamber, the lowest daily percentage of oxygen found being just above 9 per cent. in each chamber. There was thus no great difference between the two chambers; the animals in the "relief" chamber had somewhat the lower oxygen pressure.

The main results at the end of the experiment —i.e., at the beginning of the seventh week—are recorded in Table III.

TABLE III.—*Conditions of Mice at End of Experiment.*

—	Receiving "no relief."		Receiving one hour's "relief" daily.	
—	18 Essex mice.	18 farm mice.	18 Essex mice.	18 farm mice.
Alive ..	6	10	16	12
Dead ..	12	8	2	6
Tetany in survivors ..	6 out of 6	10 out of 10	14 out of 16	12 out of 12
Loss of weight in survivors	12 %	22 %	9 %	16 %

As regards deaths, far fewer of the Essex mice died in the "relief" chamber than in the "no relief" chamber, the number of deaths being 2 and 12 respectively; but such a marked difference was not observed in the case of the farm mice, there being eight deaths in the "no relief" chamber and six deaths in the "relief" chamber.

The general conditions of the survivors were compared as regards loss of weight, presence of tetany, and general appearance. All the animals were obviously subnormal; but two of the Essex mice in the "relief" chamber were in fairly good condition and might have tolerated the low oxygen for a longer period; the healthy appearance of the coats of these two mice was maintained, but their movements were somewhat sluggish, although they could climb. All the other survivors showed definite tetany when disturbed, so that the "relief" did not appear to have helped much in this respect. As regards general condition, the "relief" mice lost slightly less weight than the "no relief" mice, both in the case of the Essex and of the farm mice. The farm mice lost more weight than the Essex mice, both in the "relief" and in the "no relief" chambers, but this may have been due merely to the fact that the farm mice were on an average two grammes heavier at the commencement of the experiment; all the mice were young, growing animals and should have gained in weight.

To sum up, then, the "relief" did not exert any great effect upon the result except as regards the number of deaths in the Essex mice and as regards the two fairly healthy Essex mice. It may have helped these two, but it is obvious that the value of breathing oxygen at normal pressure for one hour daily did not appear significant, so that a longer period than one hour would be required.

Summary and Conclusion.

So far as the evidence goes, some rabbits, rats, and mice are more resistant to prolonged exposure to low oxygen pressure than is man. Mice previously acclimatised in some degree cannot maintain normal health after a month's exposure to oxygen at 10 per cent. of an atmosphere (20,000 feet). This agrees with the evidence available from expeditions to very high altitudes. From numerous experiments (see also [6 7]) it was obvious that the most resistant animals deteriorate when exposed for prolonged periods to oxygen pressures about 10 per cent. or under, and there did not appear to be any great difference in this respect between exposure to 10 per cent. (20,000 feet) and 7·5 per cent. (29,000 feet). This is to be expected from the shape of the oxygen dissociation curve, the loss of a given volume per cent. of oxygen from the blood to the tissues at low oxygen pressures in the arterial blood producing not a very great difference between the oxygen tensions within the tissues in the two cases under consideration—namely, whilst breathing oxygen at 10 per cent. and at 7·5 per cent. This was actually demonstrated by measurements of tissue oxygen tensions in acclimatised rabbits.[6] The shorter the time spent below 10 per cent. oxygen pressure in the air (or above 20,000 feet), the less will be the deterioration.

Breathing oxygen at normal pressure (about 20 per cent.) for one hour daily did not greatly increase the resistance of the animals to low oxygen pressure, so that if oxygen is to be used at normal pressure at high altitudes it must be breathed for a longer time than this. This would involve a large increase in transport of oxygen, apparatus, &c. Recent improvements, however, have rendered such apparatus much lighter than formerly.

It is difficult to estimate the powers of resistance to prolonged exposures to these very low oxygen pressures without a severe test. The choice of animals is, of course, more or less haphazard compared with that for climbers. Nevertheless the behaviour of the more resistant animals may with justice be compared with that of the specially selected climbers.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The Yale Institute of Human Relations.

THE history and development of this Institute is described in a recent address by Prof. M. C. Winternitz, dean of the Yale Medical School. While the medical school was concerned with the early treatment and prevention of mental disorder, Dr. Arthur H. Ruggles was building up a mental hygiene service for the benefit of the 5000 students in the University. Problems of behaviour were also of interest to other departments in the University, such as the department of psychology located in a different part of the city from the medical school. The Dean of the Law School, who as secretary of the University had been associated with the attempt to secure a secretary for the student body, became interested in the study of the causes underlying infractions of the law. He added a psychologist and a sociologist to his staff. So the need for a central institute for the study of man became apparent. Here will be represented biology with its applied sciences of medicine, public health, nursing, and sociology, with its allied law, business, industry, religion, &c. There are to be beds for 50 "guests" at the institute. The guests will include some for whom detention has been prescribed in the interests of society, others from the general wards of the hospital or from the out-patient department, others again will be referred from the Juvenile Court. Some may enter of their own free will. None will come against his own wish. There will be recreational facilities as well as laboratories.

Not only will professors from several different fields meet here to exchange viewpoints and contribute new light to the general problem, but students also in such widely different fields as medicine, law, and business administration will find in the institute a place where their diverse interests overlap.

Training of Negro Doctors.

There are two medical schools in the United States of America devoted exclusively to the training of negro students: Meharry Medical College and Howard University. The capacity of these two schools together is not more than 100 graduates per annum. It is estimated that there were 94 coloured students in the medical schools of the North and West in 1928. This means that at present not more than 120 negro doctors can be supplied yearly. Even so the difficulties of assigning senior students to clinical work in northern hospitals are very great—so great as to have led to the suggestion that they should be transferred to the already crowded schools for negro medical work already referred to. Yet the need for negro physicians is very great, especially in the south. For example, in Tennessee the death-rate among whites for 1927 was 10·2, while that for the negro population was 19·3. In the cities these two rates were respectively 15·3 and 28·8. In public health work it is urged that the negro physician and sanitarian understands the "psychology" of the negro people and can better secure their coöperation than a white health officer.

At the thirty-ninth annual meeting of the Association of American Medical Colleges held recently the following resolution was introduced by Dr. E. P. Lyon, dean of the University of Minnesota Medical School, and was carried unanimously.

> *Resolved:* That the Association of American Medical Colleges recognises the need for better facilities for the education of negro physicians and nurses: that the attention of philanthropic citizens and foundations is directed to the opportunities afforded in the field of negro medical education; and that we particularly call attention to the excellent work being done against great odds at the Howard University Medical School and the Meharry Medical School, and to the many needs of these institutions for buildings, hospital facilities, equipment and endowment.

The two negro colleges are carrying on work of great value under difficulties. Howard University recently completed successfully a drive for a one-half million dollar endowment for its medical school. More than 60 negroes gave $1000 each to this fund. Sixty-one per cent. of the students registered there last year had a baccalaureate degree. A campaign is now under weigh in Chicago for an endowment of three million dollars. A million needed by the University for teaching and research has been given by John D. Rockefeller through the General Education Board. The Provident Hospital, where the nurses and medical students gain their clinical experience, has received a grant of three-quarter million dollars from the Julius Rosenwald Fund. It is hoped to raise the balance of the endowment by public subscription during the present month.

Ultra-violet Solarium for Cornell University.

Dr. Smiley, medical adviser to Cornell University, and Dr. G. H. Maughan, of the department of physiology, have satisfied themselves as the result of experiments carried on over several years that ultra-violet irradiations do inhibit to a considerable extent the development of the common cold. An elaborate solarium equipped with 16 fifty-inch mercury tubes and five carbon arc lamps has been provided. It is said to be the first installation of its kind in an American University.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Marriage Statistics in the Free State.

THE Section of the Report of the Census of the Irish Free State for 1926 dealing with Conjugal Conditions was recently issued. It contains much interesting information. The most striking point is that there is a larger proportion both of unmarried males and of unmarried females in the Irish Free State than in any other country in the world of which figures are available. Of males between 25 and 30 years 80 per cent. are unmarried; between 30 and 35, 62 per cent.; between 35 and 40, 50 per cent.; and between 55 and 65, 26 per cent. Women also marry late, but not so late as men. Of women between 35 and 40 years of age 42 per cent. are unmarried. The percentage of unmarried women at each age-period is approximately three times that in America, and 50 per cent. greater than in England and Wales. The rate is much higher, both for men and women, in rural than in urban areas. Though marriage is late the number of children in proportion to the marriages is high, and has shown almost no change in the past 60 years, while in many countries, including England and Wales, there has been a great falling-off in the numbers. The late marriage age has another effect, in that the number of orphans is unduly high in the Irish Free State. Again, the age of marriage of the male being much higher than that of the female, the number of widows in the Irish Free State is high. It is noted that the more rapidly a population increases the smaller the proportion of old people in the community; while in a decreasing population the proportion is large. In conformity with this general principle it is found that the proportion of people over the age of 65 in the Irish Free State is higher than in any other country the figures for which are available. It follows that an old-age pension scheme is a proportionately heavier burden in Ireland than anywhere else.

The form in which Mr. John Hooper, Director of Statistics, and his colleagues, are issuing the Census Report is deserving of high praise. The facts are plainly set out, and are easy to arrive at.

Dinner of the Royal College of Surgeons.

The Charter Day dinner of the Royal College of Surgeons in Ireland was held last Saturday evening in the College Hall, with the President, Prof. Andrew Fullerton, presiding. The Governor-General of the Free State was the principal guest. The President spoke of the loss the College had sustained by the untimely death of his predecessor, Prof. T. E. Gordon, last July. He paid a sympathetic tribute to Mr. Gordon's work both as surgeon and as teacher. The Governor-General, speaking confidently of the future of the Free State, drew attention to the extensions and improvements that had been made in several of the Dublin hospitals during the past year. His Excellency is much interested in improving facilities for helping the sick, and before reaching his present high position had written on the subject. A pleasing interlude in a pleasant evening was the presentation by the Council of the College of silver cigarette cases to two students of the College School, Dr. Paul Murray and Mr. M. Crowe, who had played in the victorious Irish Rugby Football Team earlier in the day. Dr. Murray had made the score which gave Ireland the victory.

The Tuberculosis Problem.

Dr. P. C. Varrier-Jones, Medical Director of the Papworth Village Settlement, gave an interesting lecture last week before the Women's National Health Association of Ireland, the Governor-General being in the chair. He said that the sanatoriums in England and elsewhere were filled as to two-thirds of their beds with "middle" and advanced cases of disease, with the result that the patients broke down when they got home. If dispensaries were devoted solely to the detection of early cases of tuberculosis, and if sanatoriums were employed for the arrest of these cases, all would be well. They were spending millions a year on the treatment of tuberculosis, but next to nothing on its prevention. Their scheme of sanatorium treatment did not solve the problem of the "middle" cases, and until a suitable environment was provided for these cases the disease would spread. He went on to show that such an environment could be created as had been done at Papworth, and the patients could support themselves by their own labour, and live fairly normal lives. He then gave, with the aid of a lantern, a detailed description of the life and work at Papworth. Further speeches were made in support of the project to establish a settlement on similar lines at Peamount, County Dublin.

Dr. Nicholas Colahan.

Galway has lost a veteran physician and teacher in Dr. Nicholas Whistler Colahan. He took his degree of M.D. of the Queen's University of Ireland as long ago as 1872. In 1877 he was appointed to the chair of materia medica in Queen's College, Galway, his colleague in the chair of medicine being his father, Dr. Nicholas Colahan. Prof. Colahan continued to fulfil the duties of this chair until some two or three years ago. He was also physician to the Galway Union Infirmary and Fever Hospital, and on the staff of the County Galway Hospital. He enjoyed a large private and consulting practice. As teacher in the College he was well known to many generations of the alumni of Galway.

Dr. Garrett Hickey.

Dr. Garrett A. Hickey, who died last week, took the licences of the Royal College of Surgeons and the Apothecaries' Hall in 1890, and spent his whole professional life in New Ross, where he was medical officer to the workhouse hospital and to a dispensary district. He was one of the leading citizens of the town, and was held in much respect and affection by his neighbours. He took an active part in medical affairs, and was for many years one of the leading spirits in the Council of the Irish Medical Association and in the Irish Medical Committee. In these capacities he was well known throughout the whole profession in Ireland, and trusted and respected by all.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Tuberculosis in Vienna.

THE chief medical officer of health, Dr. Goetzl, has lately given an instructive account of the campaign against tuberculosis in Vienna. All the age-groups, he says, show a distinct decline of morbidity, except those aged 50 and upwards. In this group males show a much higher increase than females. The municipal authorities in their campaign depend largely on compulsory notification, and reports of cases discharged from hospital, which can be supervised at welfare centres. In 1927 the insurance organisations were asked to notify to the Austrian Society for Fighting Tuberculosis any infective cases of tuberculosis coming to their knowledge, and as a result of their coöperation, 744 sources of infection were reported in 1928, only a few of them having been under observation by the Society previously. Another means of detecting a focus of infection is by way of an infected child. In the case of 1094 infected children an intradomiciliary source of infection was discovered in 613, and an extradomiciliary source in 150 cases. In 331 cases none could be traced. The list of infectious tuberculous patients in Vienna amounts at present to 5300 persons. Very interesting was Dr. Goetzl's information about the attempts made to improve the housing conditions of infectious patients. In 1928, he said, out of 1272 dwellings, no less than 780 (over 61 per cent.) badly required such improvement. In 342 cases the infectious conditions were removed; in 96 the infectious patient could be permanently taken away, and in 45 the desired object was attained by finding another home for the threatened children. In 22 cases it proved possible to procure a healthy dwelling with a separate bedroom for the patient. A separate bed for the patient, at a satisfactory distance (2 metres) from the other beds was arranged for in 101 cases. It is noteworthy that in 149 cases the patient was refractory to all instructions and refused to take the advice of the medical officer. In some other cases the negative result was due to the impossibility of obtaining a suitable lodging or of sufficiently separating the patient from his family within the home.

Operations on Injured Hearts.

Acting on a suggestion of the celebrated surgeon Eiselsberg, it has become the custom here to demonstrate in the Gesellschaft der Ärzte every case of injury of the heart which has been operated on. Thus at the last meeting Dr. Schey showed two men, on whom he had performed a cardiac operation and gave the details, which were briefly as follows :—

A youth of 18 was brought to the hospital with severe cyanosis and dyspnœa; the radial and carotid pulses were not perceptible, the cardiac sounds were inaudible, and there was no hæmothorax. A stab wound was visible in the fourth intercostal space, and an operation was performed at once (20 minutes after the injury was inflicted). No pulsation was seen on the exposed pericardium, but a small stab was seen on the anterior wall, closed by a clot. The pericardium was opened, the clot was removed, and then the heart began to beat and a profuse bleeding set in. By means of a catgut suture the heart was pulled forward and thus the bleeding wound in the anterior wall of the ventricle was exposed and could be closed with three sutures. But for a pleural empyema of short duration the patient made an uninterrupted recovery, and he has remained healthy ever since.

In a second case, which proved fatal, the symptoms of cardiac injury were so far absent that it was at first doubted whether the heart was damaged at all. There was no shock, no cyanosis, no dyspnœa, and no increase of the cardiac dullness; the murmurs were quite distinct and the pulse normal. But in the next 30 minutes symptoms of a rapid internal hæmorrhage appeared, a diagnosis of pulmonary injury was made, and the thorax was opened. Only then was the cardiac injury found, and it was apparent that the lungs were uninjured. The patient died, 10 hours after operation, from embolism of the brain—a very uncommon complication.

In a third case an unexpected thing happened. At the end of an operation for a stab wound of the heart a needle was dropped into the pericardial cavity and disappeared behind the heart. Only after a prolonged search was it recovered, with the bare hand, having travelled down to the point of origin of the great vessels.

In the discussion following the demonstration, Dr. Popper related his experience of heart surgery. A patient with a revolver injury of the heart showed an entry wound on the left cardiac margin, but the place of exit of the bullet was not found, for the heart suddenly stopped beating when it was pulled forward for examination. The operation was completed without trouble after vigorous massage of the heart. A radiogram, taken after three weeks, showed the bullet situated on the right posterior cardiac wall, just between the two ventricles. The patient made an uneventful recovery with the exception of a slight pneumonia. In another case the patient had four wounds, two of which had penetrated the pericardium, and showed severe symptoms of cardiac hæmorrhage. The main injury was on the tip of the heart and was closed with catgut. This patient also made an uneventful recovery, showing that the surgery of the heart is rapidly becoming a simple matter of routine.

Voronoff's Operation in the Vienna Old Age Asylum.

For about a year several pupils of Dr. S. Voronoff have been experimenting on a few inmates of the Vienna asylum for the aged with the object of ascertaining the efficacy of Voronoff's much-discussed method of rejuvenation. A number of old men were selected, who after careful examination by a neurologist, a physician, and a urologist, were thought fit for the test—that is to say, whose mental and physical condition were such that a good result might be expected. In only one case—a man of 74—has the implantation of testes of a baboon resulted in restoration of mental and physical activity. Six weeks after the operation the patient, who had shown marked signs of senility, was able to resume his work in the garden; the tremor of his hands had disappeared, he felt quite fresh, and even his libido had returned. But the surgeon, Dr. Bachrach, who performed the operation, could not see any of the other evidence of rejuvenation—such as new growth of hair and disappearance of wrinkles—which Voronoff mentions. Even in this solitary favourable case the improvement was not permanent, and some of the troubles of senility soon returned. In the other cases operated on the results were either absent or so slight as to be negligible. In a few men there was a little improvement, which might be attributed to suggestion, but was not maintained at a control examination some months later. Bachrach thinks that the advanced senility of the inmates of the asylum was chiefly responsible for the negative results. The selected patients had no reserve forces, and the presence of such reserves is a sine qua non for the reactivation of manhood. The experiments thus show that only the *ageing* organism is fit for regeneration; when the body is already quite senile, no good results can be expected. But in the other group favourable results are obtainable if we do not hope for too much. So far as is known all evidence of rejuvenation disappears within a few years.

Recent Advances in the Treatment of General Paralysis.

As G.P.I. is a chronic disease with spontaneous remissions, one cannot be sure of real improvement until after prolonged observation of a large series of cases. Treatment with malaria and recurrent fever passes this test, but all the later methods are still on trial. The Vienna school usually augments the specific treatment by adding a course of salvarsan up to 5 grammes. In cases refractory to malaria, and in a relapse after malaria, infection with recurrent fever proves almost as effective. Infection with rat-bite fever is similar but has not yet been adequately tested. The other methods with injection of living organisms into the circulation have proved, in the hands of the Vienna clinicians, quite valueless and even dangerous. Sulfosin (a suspension of 1 per cent. pure sulphur in olive oil) is painful and useless.[1] Intravenous injection of 10 c.cm. of a 20 per cent. solution of sodium chloride (Valinsky) followed by a hot bath and pack, produces fever, but has been tested only in a few cases, and cannot be judged correctly. The same holds good of prolonged hot electric baths (Chvostek). Other experiments have been made with large doses of salvarsan, with tryparsamide (as reported from America), and with phlogetan and sodium nucleinicum. All these have given very little success and have been ineffective in many cases. Whatever treatment is to be given it is essential to secure the earliest possible recognition of this dangerous condition, and this can only be done by laboratory tests. It may be safely assumed that patients with a healthy liquor are rarely if ever in danger of acquiring a metaluetic affection. Therapeutic effort must therefore be directed towards making the liquor normal. So far malaria therapy stands alone as a safe means to this end, the favourable results in early cases reaching as much as 80 per cent. It has been shown that the degree and duration of the fever produced by malaria play an important part.

---

[1] Favourable results with sulfosin have been described by K. Schroeder in our columns (1929, ii., 1081).—ED. L.

DONATIONS AND BEQUESTS.—Mr. George Douglas, J.P., of The Bield, Bentinck-drive, Troon, Ayrshire, left £500 each to Broomhill Home for Incurables, Kirkintilloch, the Royal Hospital for Sick Children, Glasgow, the Royal Samaritan Hospital for Women, Glasgow, and Kilmarnock Infirmary.—Mr. David Reuben Sassoon, of Queens-gardens, Hove, among other bequests, left £1500 to King Edward's Hospital Fund; £500 to the Sussex County Hospital; £400 to the Royal Alexandra Hospital for Sick Children; £250 to the Brighton, Hove, and Preston Dispensary, and the Hove Hospital; £100 to the Royal Surgical Aid Society; and £1500 to the Spanish and Portuguese Jews' Hospital.—Mr. Keith Ramsay-Maitland, of Edinburgh and Dunbar, left £500 to the Dunbar and District Hospital; £200 to the Dunbar, Belhaven, and Spott District Nursing Association; and on the expiration of a life-rent, the following legacies: £2000 each to the Royal Infirmary, Edinburgh, and the Royal Edinburgh Hospital for Sick Children; £1000 each to the Convalescent Home, Murrayfield, the Royal Edinburgh Hospital for Incurables, the Royal Blind Asylum and School, Edinburgh, and Queen Victoria's Jubilee Institute for Nurses, Scottish branch.

PSITTACOSIS.

A MEMORANDUM FROM THE MINISTRY OF HEALTH.

A MEMORANDUM on psittacosis has been issued by the Ministry of Health (151/med.), calling attention to the prevalence and characteristics of the disease, the precautionary measures which should be adopted against its spread, and the investigations in progress and contemplated into its ætiology and epidemiology.

Prevalence.

Since July, 1928, some 30 or 40 suspected cases have been brought to notice in England, principally in Cheshire, Warwickshire, and the London district. Numerous cases of human psittacosis have recently come to notice in South America, the United States of America, Germany, Austria, Czecho-Slovakia, and Switzerland.

Characteristics of the Disease.

Acute illness due to infection by parrots has been described from time to time in medical literature since Ritter first called attention to an outbreak in Switzerland in 1879. In England, cases have been recorded by Beddows (1914), Gulland (1924), and Thomson.[1] In general, the disease in human beings takes the form of an illness, usually acute, with typhoidal and pneumonic symptoms. The pulmonary condition varies from a slight bronchial catarrh to massive consolidation of whole lobes of the lung; the "typhoid" symptoms may be severe or consist merely of headache and pyrexia, though frequently epistaxis, rose spots, abdominal distention, and, sometimes, diarrhœa are also present. The illness has frequently lasted many weeks, and in not a few cases has been fatal.

The bacteriology is at present far from clear. *B. psittacosis* isolated from a sick parrot by Nocard in 1892, and by Perry in 1920, was found by Perry to be identical with *B. aertrycke* (Mutton). The presence of this organism has not been established so far in any of the recent English cases, or in the birds associated with them. Quite recent research points to a filtrable virus as the infecting agent of certain of the London cases (THE LANCET, Feb. 1st, 1930, p. 235), though it is as yet too early to say what significance these discoveries have.[2]

Circumstances of Occurrence.

The usual history is that a patient with an illness resembling typhoid, or more rarely with an atypical pneumonia, is found on inquiry to have been in close contact with a sick parrot, parrakeet, or love bird. The incubation period in the person attacked may be as long as ten days. Transmission of the disease from one human case to another has occasionally been suspected but has not been definitely proved. The cases of human illness have mostly been infected by recently imported birds, the conditions favouring the bird disease being overcrowding, fouling of food, water, and cages.

Apparently infection from bird to bird may occur in this country; epidemics are unknown, however, at the Zoological Gardens in London, and even on the premises of bird dealers, where hygienic conditions are less favourable, outbreaks are uncommon. Infection may persist for periods up to four months in an apparently healthy bird.

Precautionary Measures.

There is no ground for apprehending danger from domestic parrots which have been kept in a household for many months or years apart from any introduction of new birds. On the other hand, this cannot be said as confidently in regard to most newly purchased birds, and the public is likely for the present to be chary in buying birds which have recently arrived in this country, or whose history is unknown to the purchaser. This caution is not unreasonable. Persons owning these pets would be wise :—(*a*) to pay attention to strict cleanliness of the cage and protection of food and water from fouling by the birds; (*b*) to scrub and disinfect all articles which have been in contact with sick birds, as well as removing these from contact with healthy birds; (*c*) to avoid fondling and petting newly acquired birds.

Investigations.

Recent cases have been under investigation, especially in and near Birmingham and in London. Medical officers of the Ministry have taken part in certain of these investigations and from their experience note the importance of ascertaining and recording certain points of detail in studying cases. These are :—

(*a*) Nature and period of the association between the human case and the parrot, and the directness of contact likely to convey infection.

(*b*) The history of the bird, so far as it can be ascertained, with dates, particularly including the date of the bird becoming ill.

(*c*) The date of the attack in the patient and the symptoms.

(*d*) Whether there has been any evidence of the association of the patient with previous human cases.

Medical officers of health, besides transmitting information on cases reported to them, can assist by :—

(1) inquiring, in all notified cases of enteric fever or pneumonia, into the possible association of the patient with sick or recently dead birds;

(2) instructing sanitary inspectors and health visitors to be on the look out for illness among pet parrots, budgerigars, &c.;

(3) Unless adequate facilities for research are available or preferred elsewhere, forwarding to the laboratory of the Ministry :—(*a*) bodies of birds which seem to have been connected with cases of human illness; (*b*) portions of liver, spleen, lungs, bone-marrow, and lymph glands, in 50 per cent. sterile glycerin, diluted with normal saline, from fatal human cases where a post-mortem examination has been made. Specimens should be dispatched in conformity with the post office regulations as regards pathological material and addressed to the Ministry of Health Laboratory, Dudley House, Endell-street, London, W.C. 2.

Information regarding cases or suspected cases of psittacosis should be communicated to the Medical Officer of Health of the district, or if desired, direct to the Ministry (Senior Medical Officer (Med. 1)).

DEATH FROM PSITTACOSIS.—At the London Hospital on Feb. 5th an inquest was begun by Deputy Coroner Dr. W. Bentley Purchase upon one of the victims of psittacosis. Mr. Dennis Sullivan, of Barking, said that the deceased, Lilian Rogers, was his sister-in-law. She was 30 years old. The house surgeon at the London Hospital gave evidence that the deceased was admitted on Jan. 28th with her brother Edward. Both were suffering from psittacosis. The other brother, James, was admitted on Jan. 30th with the same illness. The parrot had been bought on Jan. 10th, seemingly ill, and died on Jan. 22nd. When admitted the deceased was comatose and had pneumonia, gradually became worse, and died on Feb. 2nd. The post-mortem examination showed that she appeared to have died of psittacosis. Apart from that she was healthy. Edward had almost identical symptoms and was not yet out of danger. The deceased's brother James was progressing favourably. When this disease was first discovered in 1896 it was thought to be due to the *Bacillus psittacosis*, but this was not brought out by subsequent investigation. There was a recorded case of transmission from one human being to another, with a history of having used the same handkerchief. The disease was not unlike typhoid, with symptoms in the lungs. Dr. Fenton, of Barking, said the parrot was bought on Jan. 10th with two others. One bird went to the Rogers family, one to Romford, and the third to a resident of Stepney. The first two birds were dead, but the Stepney one had been secured by the London Hospital alive, but very ill. The deceased was taken ill on Jan. 23rd and Edward on Jan. 25th. The latter went to bed with a temperature of 102·6° F., suffering from photophobia and severe headache. The Deputy Coroner said this was not an inquiry which he could finish that day. He desired some more information, and adjourned the inquest until March 4th.

---

[1] THE LANCET, 1929, ii., 117.

[2] An amplification of the preliminary note published by Dr. Bedson, Dr. Western, and Dr. Levy Simpson in THE LANCET of Feb. 1st will be found on p. 345 of the present issue. Further reference to psittacosis will be found in our Parliamentary Intelligence columns.—ED. L.

Correspondence.

"Audi alteram partem."

RADIUM OR EXCISION FOR EPITHELIOMA OF THE TONGUE.

To the Editor of THE LANCET.

SIR,—Mr. Ogilvie's letter contains a fallacy which appears likely to provide difficulties whenever any attempt is made to compare statistically the results of surgical treatment with those of treatment by radium, in that he does not take into account the operability rate. To compare Regaud's figures, which are based on cases of which only some 20 per cent. were operable when submitted to treatment, with those of surgical excision which were necessarily all operable, is to reduce statistical comparison to the absurd. A further point which appears to me to be of far greater importance than statistics can ever convey is the fact that the patient treated by surgery is necessarily a mutilated patient, the one treated by radium is not. Actually the time has not yet come when statistical comparison between surgery and radium can fruitfully be made, but if we consider the patient as a human being rather than as a unit in a group of figures, then, in the case of cancer of the tongue at any rate, there can be little doubt as to which method has the most to offer him.

I am, Sir, yours faithfully,
E. G. SLESINGER.
Wimpole-street, W., Feb. 9th, 1930.

THE SALE OF WEED-KILLER.

To the Editor of THE LANCET.

SIR,—I wish to direct your attention to a matter of grave importance—it is this: although no lay person can obtain poisons from a chemist without giving his or her name and address, anyone can go to an oil shop and purchase enough weed-killer to end the days of 50 persons without being asked any questions. In the inquest on the Stanley family it was stated that a teaspoonful of weed-killer was a fatal dose, and that mixed with ordinary food it was quite tasteless. What a terrible state of affairs this is, and how unsatisfactory for the medical profession; a doctor cannot know that the patient has taken weed-killer until he has had the vomit analysed, but by that time the patient is dead, so that nothing can be done for him. I trust you will use your influence to have this state of affairs altered as soon as possible.

I am, Sir, yours faithfully,
ERIC CLINE, M.R.C.S. Eng., L.R.C.P. Lond.
Weybridge, Feb. 8th, 1930.

*** Our correspondent rightly draws attention to the perilous ease with which weed-killer can be purchased. The law is not now so vigorous as in the time of Henry VIII. when, after a deplorable incident in the Bishop of Rochester's household, Parliament imposed on persons found guilty of wilful poisoning the penalty of being boiled to death. Nowadays, in spite of restrictions on the sale and possession of poisons and "dangerous drugs," a would-be murderer can easily equip himself with a tin of the right stuff at an oil store. The Arsenic Act of 1851 is still upon the statute-book, but Section 2 of the Poisons and Pharmacy Act of 1908 seems more anxious to encourage the sale of sheep-dip and weed-killer than to protect His Majesty's lieges from being poisoned. The Section provides that sale is to be under licence of the local authority and subject to regulations. It is commonly said that local authorities take these responsibilities lightly and that the few formalities required by the regulations are neither widely known nor invariably observed. Facilities for buying sheep-dip and weed-killer are commercially desirable, but are there no prospects of non-poisonous preparations being produced which will satisfy the requirements of farmer or gardener? Quite apart from statute, there is a common-law duty of persons who possess poisons to take good care that they are so securely kept as not to be a source of injury to others. If it be true that weed-killer is sometimes sold to minors or others without adequate inquiry, it would seem that this common-law duty is not discharged.—ED. L.

BERI-BERI IN A WHALING EXPEDITION.

To the Editor of THE LANCET.

SIR,—I was much interested in your annotation (p. 250) on Dr. Nissen's experience of beri-beri in an antarctic whaling expedition. During the 1927–28 season I was in the antarctic as medical officer on a whaling ship and was called on several occasions to other ships to see cases of beri-beri. I had with me a very limited quantity of marmite which I gave in small quantities to these cases. The improvement shown in the few days prior to the men being sent to the base was so striking that I put in a strong recommendation to the company that in future all their ships should have an adequate supply of marmite on board, to be used for the prophylaxis of beri-beri. This has, I believe, been done with excellent results.

I am, Sir, yours faithfully,
Edinburgh, Feb. 5th, 1930. JOHN B. ROLT, M.B.

SPINAL ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—Dr. Howard Jones says the explanation of the escape of the phrenic motor roots when numbness in the neck follows a novocain injection is simple; and he suggests that it is as follows:—

> "(1) The upper remnant of a heavy solution tends to affect the posterior roots more than the anterior."

Quite so, but I am using a lighter solution. Clouds of witnesses will testify to this. They have seen the cerebro-spinal fluid as it comes into the syringe drop by drop fall to the bottom leaving the spinocain or May and Baker's solution at the top. The tendency therefore would be for it to affect the anterior roots.

> "(2) The concentration in the cervical region is too dilute to affect motor fibres."

A few months ago I saw a patient unconscious, analgesic from head to foot, and pulseless, whom the surgeon declared to be dead—not only dead, but that he smelt dead (this was partially true, for he had four feet of completely gangrenous gut inside the abdomen)—whom I declared to be alive, simply on the grounds that he was breathing regularly, albeit quietly. This ground proved to be solid rock, and he recovered. Here, then, apparently Dr. Jones and I are agreed, that the concentration in the cervical region is too dilute to affect the motor fibres. But the concentration used was amply sufficient for all operative procedures. In other words, in the concentration commonly used and necessary, novocain paralyses receptors, leaving the phrenic motor roots, nerves, and diaphragm active.

One case is not enough, so let me quote Jonesco, who, using mostly stovaine, but also novocain, records 1387 cases which he injected "au dessous de la proéminente," with successful analgesia without fatality. Here again the concentration in the cervical region was too dilute to affect the motor fibres—for all these patients must have breathed. The paper of Koster and Kasman, to which you referred in your issue of Jan. 18th (p. 145), shows that novocain will not paralyse the phrenics; it does not offer any explanation of the paralysis of the abdominal muscles. I think it is a fair inference from their paper to suppose that in the strength used novocain paralyses abdominal muscles merely by cutting off afferent impulses. In any case I am not sure that the explanation is as simple as Dr. Jones suggests.

The matter is one of great importance. The present objection, and a very real one, to spinal analgesia for upper abdominal surgery, is due to the fact that manipulation of viscera sets up afferent impulses in the vagus. These impulses always cause more or less distress; usually the distress can be borne, it depends on the patient. If we could safely anæsthetise the vagus, there would be no more objection to spinal analgesia for upper abdominal work than there is now for (say) a hernia, or the amputation of a toe. Consciousness is hardly an objection. If it could be definitely established that novocain paralysed receptors only in a strength which would produce complete analgesia, the problem would be solved. Jonesco, Kasman, and Koster seem to have done it.

I am, Sir, yours faithfully,

Manchester, Feb. 11th, 1930. E. FALKNER HILL.

CO_2 FOR PULMONARY AERATION.

To the Editor of THE LANCET.

SIR,—May I call attention to what is presumably a slip in Dr. Fuller's article on Post-operative Pulmonary Complications in THE LANCET of Jan. 18th (p. 121)? If " 50 per cent. CO_2 in air " was actually given, it is hardly surprising that patients would not tolerate it, for 5–10 per cent. is the concentration commonly employed, and it is very doubtful if higher concentrations could be tolerated by conscious persons for any length of time.

I am, Sir, yours faithfully,

R. J. CLAUSEN.

Clifton Hill, St. John's Wood, N.W., Feb. 2nd, 1930.

A FACTORY CLINIC.

To the Editor of THE LANCET.

SIR,—The opening early this spring of a factory clinic in the Swiss mountains for certain victims of tuberculosis coincides so nearly with the publication of last year's preliminary vital statistics that one may be forgiven for suggesting that the Ministry of Health might do worse than explore the possibilities of the Swiss idea for adaptation amongst ourselves.

At Leysin, 4500 feet above sea-level, there is now being completed, under the direction of Europe's most eminent practitioner of sun healing, Dr. Auguste Rollier, a series of open verandah workshops several stories high. All the beds are provided with work-tables and special apparatus to allow the patients, who are surgical cases, to work in any position required for their cure. Here in the open sunlight, or, when the cold winds come, behind vita-glass windows letting in the natural ultra-violet rays, they will turn out watches, stockings, pottery, speedometers for aeroplanes and motors and other products, all at the usual industrial rates. I am told that the work for some time to come has already been contracted for.

If we mean to mend the grave situation disclosed by last year's figures for births and deaths, in which the part of the white scourge must have been dire, here surely is an agency full of hope not less from the point of view of prevention than from that of actual cure.

I am, Sir, yours faithfully,

House of Commons, Feb. 10th, 1930. H. H. LAWRIE.

HALIFAX INFIRMARY.—Last year this hospital treated 4114 in-patients. Their average stay was 17·6 days, a minute fractional increase upon the figure of the preceding year. Each one cost £5 5*s.* 11*d.*, as against £5 3*s.* 6*d.* in 1928; the cost per occupied bed was £130 1*s.* 2*d.*—in the preceding year it was £129 6*s.* 7*d.* The maternity cases numbered 360, and 340 children were born. Motor accidents treated numbered 120; they cost £1300, and occupied ten beds during the whole of the year—one patient was admitted in June, 1928. Workpeople's contributions reached the high-water mark of £9659.

Obituary.

JOHN WRIGHT MASON, M.B.E., M.B. ABERD., D.P.H.

THE death of Dr. Wright Mason, in his seventy-eighth year, leaves a gap in the ranks of the pioneers of sanitation in this country. It is now nearly 50 years since he was appointed medical officer of health for Hull—now the city of Kingston-upon-Hull—and under his guidance the department which he controlled grew from almost a single-handed affair to one containing some 600 persons. He took a keen interest in all developments of public health work—though he had misgivings about the wisdom of some of its more recent advances—and his knowledge of infectious diseases and what is now called environmental hygiene was unsurpassed. He had dealt with cholera, plague, and serious small-pox epidemics, and he was responsible for the erection of one of the finest disinfecting and contact stations in the country. His chief loves were, however, medico-legal work and port sanitation. Until a few months of his retirement in 1925, he acted, single-handed, as police surgeon to a force of some 1000 men: he took a daily sick parade and spent much time visiting sick policemen in their homes. He had a wonderful collection of specimens from cases of medico-legal importance, and an honour which he esteemed highly was that of Examiner in Forensic Medicine in the University of Edinburgh. He was an authority on port sanitation, was one of the founders, and for some 30 years the honorary secretary and treasurer of the Association of Port Sanitary Authorities of the British Isles. He was always too busy to have many hobbies, but he took a great interest in the Volunteer movement, Freemasonry, and the collection of old armour. He resigned his public offices in March, 1925, and was the recipient of many gifts. His wife predeceased him by two years. He lost a son in the war, and is survived by four sons and a married daughter.

JOHN KEKWICK, M.R.C.S. ENG., L.D.S.

Mr. John Kekwick, whose death occurred on Jan. 27th, was a Carlisle man, and succeeded to a practice which had been founded by his father, and carried on by his uncle. He was educated at the Middlesex and Royal Dental Hospitals, being house surgeon at the latter hospital after qualifying in 1891. His practice was a very extensive one, his name being well known and much respected throughout the Border Counties. He held the position of dental surgeon to the Cumberland Infirmary from 1899 to 1911, and returned again in 1914, at the outbreak of the late war, when the hospital staff was depleted by war service. An active member of the North of England Odontological Society and British Dental Association, he retired from practice only six months ago, after a long illness, but for some years he had made his home in the country. He was an enthusiastic gardener, the countryside always appealed to him, and he had many friends amongst the agricultural community. He leaves a widow and three sons, of whom the second is a medical student at Cambridge.

" ABUSING " THE NAME OF A HOSPITAL.—In deciding to support a contributory scheme for the benefit of the Warneford Hospital, the Leamington Chamber of Trade protested against what was described as the " abuse " of the name of the hospital by organisers of entertainments on its behalf, who inundated the members with request for gifts towards whist-drives, &c. These very numerous entertainments last year produced only £204 for the hospital. It was stated that a large proportion of the proceeds was swallowed up by expenses and that balance-sheets were not sent to the hospital. It was decided to make representations to the hospital committee on the subject, it being thought that every entertainment in aid of the funds should be officially sanctioned.

HOUSE OF LORDS.

WEDNESDAY, FEB. 5TH.

PSITTACOSIS.

The Earl of **ONSLOW** asked the Government how many cases of psittacosis or "parrot disease" had been recorded since June 1st, 1929; what steps had been taken to prevent the spread of the disease, and whether there were any restrictions imposed on the importations of parrots, and, if so, of what nature?

Lord **DAWSON** said he desired for a few minutes, before the answer was given on behalf of the Government, to draw attention to a few facts. He did not do so in any critical spirit, because the present health administration of the country had rightfully the confidence of the public. This was not really a new disease. It was a disease which had been known for some time, but it was new in this respect that it had recently become a matter of some anxiety in certain districts of England. There was no fear of it becoming rapidly diffused, like influenza. It would not spread in that universal way, but it would spread in patches. It was a disease which broke out among small communities of people and families, but in the patches where it did appear they were liable to get a mortality which was very depressing. He would illustrate that by this instance. A boy bought a parrot a little while ago—because the incubation period was anything from ten days to three weeks—and it was noticed by his mother that the parrot was not very well. The mother attended to the parrot and cleansed the bird's eyes. The bird died, and a daughter who had never had any contact with the parrot during its life, took the body and deposited it in the dustbin. The girl who had removed the body of the parrot died after a week's illness, and at the present time the mother and two sons were gravely ill from the disease. That was apt to give a very serious importance to this disease, because it was liable when it did break out to have somewhat dire results. On the other hand, it did not carry with it any necessary anticipation of a widespread epidemic like influenza.

It was mainly the parrots of South America which were responsible for the disease. Some months ago 500 parrots were dispatched from Argentina to France. Some 200 of them died en route, and the presumption was that the remaining 300 were not desirable visitors to the French Republic, for the result of their being landed was that France had an outbreak of this disease; and Argentina itself had an outbreak last July. It seemed that there were two courses open for consideration. Of course the Ministry of Health knew the difficulties of each of them better than other people. One was to put the parrots into quarantine. There always was a lighter side even to serious happenings. He pictured a quarantine of parrots. He hoped they would be in some *remote island, like Lundy* Island, because they would provide serious entertainment for those who survived. If they were to put on to that island certain members of His Majesty's Forces they would find that those who survived had a knowledge of language which would make them highly saleable when this epidemic had passed. The alternative to that was an embargo. He *knew that that* was a dangerous word to those who used it in a political sense. But they had to put an embargo on diseased meat, and animals which were likely to be diseased when they were killed, and *he suggested for the* consideration of the Government whether seeing that a parrot was, after all, a luxury, and that now, if the parrots arrived in this country, the public would put them out into the streets, as they had been doing frequently already, it was not almost better to put an embargo on the importation of these parrots for a reasonable time till the disease was past. He thought that the mere announcement by the Government that they were going to introduce an embargo would probably put a stop, for the time being, to their dispatch here from Argentina. In view of the experience of 500 parrots being dispatched to France, 200 of which had died en route, they were really unnecessarily spreading a disease unless they took action. He thought that it was very important that no alarm should arise over this question, beyond what was proper and fitting.

Lord **MARLEY**, replying for the Government, said that he was sure that the House would welcome the intervention of Lord Dawson who was able to speak with such authority on this matter. The noble lord had paid a tribute to the work of the Ministry of Health which he was sure their Lordships would agree was well deserved. In the first place psittacosis was not compulsorily notifiable, and consequently they had no complete records of the disease. Since June 1st last the Ministry had received information of 40 cases in this country, in some of which the available particulars established only a suspicion of the disease. The Ministry were advised that the danger of the spread of the disease from human contact was practically negligible. If there were, for example, no parrot in a house the occupants of that house would appear to be safe. To deal with the spread of the disease, therefore, they had to rely upon precautions adopted with regard to the parrot itself. The Ministry were advised that the matter might become serious; they had therefore prepared a memorandum setting forth such information as was available with regard to the disease and the precautions which should be observed in the care and handling of parrots. The memorandum would be circulated shortly to local authorities and would be on sale. There were at present no restrictions on the importation of parrots. He did not think that any member of H.M. Forces would welcome being placed on Lundy Island with imported parrots, and he was not quite certain to which—the parrots or the members of H.M. Forces—Lord Dawson had referred when he said that they would learn bad language. But he (Lord Marley) was advised that under the existing law restrictions could only be imposed if it were established that measures were necessary *in* order to prevent the spread of the disease. The Ministry of Health felt that further information was necessary before they would be justified on grounds of health in imposing restrictions on importations. They were further informed that practically no commercial consignments of parrots reached the country *during the winter months.*

HOUSE OF COMMONS.

WEDNESDAY, FEB. 5TH.

Medical Examinations for Entrance into the Navy.

Mr. W. G. **HALL** asked the First Lord of the Admiralty if he was aware that boys who had passed the educational test and two medical examinations for entry into the Navy were liable to rejection by a third medical examination on entry; and if he would see that the first medical test was made more thorough in order to avoid expense to parents and disappointment to boys.—Mr. **AMMON** replied: I assume my hon. friend is referring to boy artificers. These boys frequently volunteer to undergo a preliminary medical examination some time before taking the educational test. Those who pass this educational test undergo an official medical examination for entry into the Service which is normally final. But those who join after a lapse of 14 days or more are again medically examined on arrival in their ship or establishment.

Deaths from Dangerous Drugs.

Major **CARVER** asked the Home Secretary whether, in view of the statement of one of the British assessors at the recent meeting of the League advisory committee on the traffic in opium and other narcotic drugs to the effect that the destruction of life caused by this traffic could be compared with that of a modern battle, he could give any statistics showing what the mortality was in this country from drugs.—Mr. **CLYNES** replied: I have seen a Press report of the remarks made by the President of the Central Opium Board. They obviously related to the world traffic in drugs rather than to the state of affairs in any one country. The Registrar-General has furnished me with the following figures relating to deaths from drugs coming within the Dangerous Drugs Acts in England and Wales, 1921–1928:—

	M.	F.	Total.
A. *Deaths from Opium and other Narcotic Drugs.*—In 8 cases (6 m. and 2 f.) death was due to "the drug habit" or the use of narcotics, but there is no information available to show whether the drugs used came within the provisions of the Dangerous Drugs Acts	18	15	33
B. *Deaths from Suicide by Opium and other Narcotic Drugs.*—In 10 cases (7 m. and 3 f.) death was due to the use of narcotics or opiates, but there is no information available to show whether the drugs used came within the provisions of the Dangerous Drugs Acts	57	22	79
C. *Accidental Deaths from Opium and other Narcotic Drugs.*—In 9 cases (5 m. and 4 f.) death was due to narcotics or opiates, but there is no information available to show whether the drugs came within the provisions of the Dangerous Drugs Acts	64	31	95
Homicide by other Means.—Morphia	—	1	—

THURSDAY, FEB. 6TH.

Prevention of Bovine Tuberculosis.

Lieut.-Colonel **FREMANTLE** asked the Minister of Health if, with a view to effective coördination of effort to prevent

Information as to the number of schemes which have started is not available.

Drinking of "Red Biddy" in Scotland.

Mr. McELWEE asked the Secretary of State for Scotland whether he was aware of the damage to health caused by an intoxicant known as "red biddy" among the industrial population in the West of Scotland; and whether he would cause an investigation to be made thereon.—Mr. ADAMSON replied: I am informed that an alcoholic concoction commonly known as "red biddy" is being increasingly consumed in the poorer areas in certain districts. I am advised that it has a most serious effect on the health of the consumer, and am having the matter fully inquired into.

Medical News.

UNIVERSITY OF CAMBRIDGE.—On Feb. 8th the following degrees were conferred:—

M.B. & B.Chir.—G. N. Wood.
B.Chir.—J. R. Peacock and S. R. Matthews.

UNIVERSITY OF DUBLIN.—The Diploma in Gynæcology and Obstetrics has been awarded to Dr. Chua Boon Teck.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—As the result of the Final Examination held from Jan. 6th to 29th the following candidates were approved in the undermentioned subjects, but are not eligible for diplomas:—

Pathology.—E. S. Asiedu-Ofei, Birmingham; H. B. Bagshaw, London; J. H. Bartlett, Cambridge and St. Mary's; Ilma B. S. Bingemann, St. Mary's; M. Bloom, Manchester; B. F. M. Bond, Westminster; W. D. Coltart and A. F. Davy, St. Bart.'s; P. T. L. Day, Guy's; C. M. Dell, St. Thomas's; P. G. Dowdell and D. G. Evans, Univ. Coll.; J. D. J. Freeman, St. Thomas's; K. H. Gaskell, Cambridge and King's Coll.; G. H. Gool, Guy's; J. O. Harrison, St. Bart.'s; Florence R. Hart, King's Coll.; D. S. Hayes, St. Bart.'s; A. R. C. Higham, St. George's; H. L. Hodgkinson, St. Bart.'s; H. R. Hovsha, King's Coll.; E. B. Jackson, Univ. Coll.; L. Jacobson, Cape and London; J. E. Jones, Liverpool; G. C. Knight, St. Bart.'s; S. R. Ledger, King's Coll.; E. H. W. Lyle, Cambridge and King's Coll.; F. G. Maitland, St. Mary's; Gladys L. Neill, King's Coll.; A. M. Nussbrecher, Middlesex; T. C. Outred, Guy's; M. Phillips, London; J. H. Pierre, St. Bart.'s; N. H. L. Ridley, Cambridge and St. Thomas's; R. S. Risk, St. Bart.'s; M. A. Robertson, Cambridge and London; K. M. Ross, St. Bart.'s; B. Rubinsky, London; C. K. Simpson, Guy's; H. Simpson, Manchester; D. J. R. Steen, Cambridge and St. Thomas's; M. R. Thomas, Univ. Coll.; G. M. Tickler, King's Coll.; D. Trimble, Birmingham; and Rose E. Williams, Royal Free.

Medicine.—S. Bochenek, St. Bart.'s; J. Britanischski, London; Amy C. E. Clarke, Oxford and Univ. Coll.; A. F. H. Coke, St. Mary's; Charlotte A. G. Conway, Royal Free; J. H. Conyers, Cambridge and St. Thomas's; H. Coorland, St. Bart.'s; Catherine B. Crane, Royal Free; R. M. S. Cross, Cambridge and St. Bart.'s; Elizabeth T. Davies, Cardiff and Westminster; P. G. Dowdell, Univ. Coll.; Margaret L. Foxwell, Manchester; G. H. Gool, Guy's; P. R. Graves, St. Thomas's; J. T. P. Handy, Univ. Coll.; Eileen E. Harvey, Royal Free; J. R. Hindmarsh, Durham; A. D. H. Hugo, Cape and Guy's; J. E. S. MacDonald, London; Joyce MacInnes and Margery L. Maltby, Royal Free; M. Mandelstam, St. Bart.'s; C. B. Melville, Melbourne and Middlesex; A. M. Nussbrecher, Middlesex; D. D. Payne, St. Thomas's; M. Phillips, London; S. Ramanathan, Ceylon and King's Coll.; N. H. L. Ridley, Cambridge and St. Thomas's; R. S. Risk, St. Bart.'s; C. G. Roberts, Cambridge and Westminster; H. E. W. Roberton, Cambridge and St. Bart.'s; J. M. Robertson, Guy's; L. Seaton, Leeds; T. Shahani, Bombay; L. Silman and S. Silman, Leeds; J. G. Sleigh, Cambridge and King's Coll.; B. Southwell, Guy's; Enid C. Street, Punjab and Royal Free; T. F. Tierney, St. Bart.'s; W. N. P. Wakeley, King's Coll.; Mary J. Westall, Royal Free; G. P. B. Whitwell, Guy's; D. A. Williams, Cardiff and Univ. Coll.; and T. C. Wilson, Birmingham.

Surgery.—K. Alman-Vtcherachnia, Royal Free; Kathleen W. Aylwin-Gibson, Liverpool and Westminster; G. N. Bailey and W. I. Bain, Cambridge and St. Thomas's; G. Balasuriya, Ceylon and Guy's; A. N. Barker, St. Thomas's; C. O. Barnes, Cambridge and St. Bart.'s; F. Bartholomew, St. Thomas's; W. L. H. L. Bell, St. George's; A. Buch, St. Mary's; A. Burkhardt, Univ. Coll.; M. L. Bynoe, King's Coll.; H. M. Chappel, Cambridge and Univ. Coll.; L. P. Clarke, St. George's; A. L. Climer, St. Bart.'s; J. H. Conyers, Cambridge and St. Thomas's; R. V. S. Cooper, Birmingham; T. R. S. Cormack, Cambridge and London; W. C. Cresdee, St. George's; W. J. D'Rosario, Guy's; R. H. Dobbs, London, J. J. Eapen, Madras and Birmingham; R. E. M. Fawcett, St. Bart.'s; F. H. H. Finlaison and R. H. Fish, Cambridge and St. Thomas's; J. D. J. Freeman, St. Thomas's; K. Ghosh, Royal Free; R. W. Graham-Campbell, Cambridge and St. Bart.'s; C. A. Grant, Cambridge and St. George's; E. R. Greathead, Cambridge and London; Rachel Gubbay, Punjab and Royal Free; S. R. Gunewardene, Ceylon and Univ. Coll.; C. J. K. Hamilton, Cambridge and Liverpool; R. M. Harvey, London; D. S. Hayes, St. Bart.'s; Geraldine J. G. Hayes, Manchester and Charing Cross; H. L. Hodgkinson, St. Bart.'s; W. Holdsworth, Liverpool; Laura M. Hollingworth, Univ. Coll.; U. M. Hopkins, Bristol; B. Horwitz and L. H. Howells, London; N. R. Jeffery, Manchester; E. N. Jenkinson, St. Bart.'s; H. B. John, St. Mary's; W. J. Johnson, Guy's; M. M. St. G. Johnstone, Cambridge and St. Thomas's; Alison F. Z. Judd, Royal Free; J. D. Kershaw, Univ. Coll.; F. P. L. Lander, Middlesex; D. H. LeGood, St. Thomas's; H. Lwow, Vienna and St. George's; W. McKissock, St. George's; F. G. Maitland, R. W. Malim, and C. E. P. Markby, Cambridge and St. Thomas's; J. H. G. Mason, Middlesex; Blodwen Morgan, Charing Cross; B. B. Nanavatty, Bombay and Royal Free; P. M. Oxley, St. Bart.'s; G. H Pearce, Univ. Coll.; F. E. Pilkington, Cambridge and King's Coll.; J. O. Poynton, Cambridge and Charing Cross; G. E. Ranawake, Ceylon and Middlesex; A. H. T. Robb-Smith, St. Bart.'s; Victoria M. Robinson, Oxford and King's Coll.; C. A. Rumball, Guy's; M. H. Shah, Punjab and Univ. Coll.; W. W. Simkins, St. Mary's; Edith M. P. Smith, Charing Cross; N. Solomon, St. Bart.'s; R. W. Stephenson, Guy's; A. El K. Talkhan, Cairo; F. H. Taylor, Durham; J. C. G. Whitelaw, Cambridge and St. Thomas's; H. W. Williamson, Cambridge and St. Bart.'s; W. E. Wimberger, Birmingham; F. S. Winton, Cambridge and St George's; F. J. Wright, Cambridge and London; and W. Young, St. Mary's.

Midwifery.—E. F. Adams, Manchester; N. W. Alexander, Cambridge and St. Thomas's; M. Ata Ullah, Charing Cross; F. G. Badger, Cardiff and London; H. B. Bagshaw, London; G. N. Bailey, St. Thomas's; I. E. Banner, Royal Free; C. O. Barnes, Cambridge and St. Bart.'s; C. R. G. Barrington, Univ. Coll.; G. P. Barua, Calcutta and London; D. A. Beattie, St. Bart.'s; J. H. Beilby, St. Thomas's; G. A. Betts, Birmingham; A. Bhardwaj, Guy's; Ilma B. S. Bingemann, St. Mary's; A. T. Blair, St. Bart'.s; B. F. M. Bond, Westminster; P. Brown, London; W. D. T. Brunyate, Oxford and St. Bart.'s; C. R. Caffry, London; G. F. Carey, St. Thomas's; J. Carlton, Guy's; H. T. Chilton, Birmingham; Amy C. E. Clarke, Oxford and Univ. Coll.; R. T. V. Clarke, Oxford and St. Bart.'s; E. C. Coaker, Oxford and St. Mary's; W. D. Coltart, St. Bart.'s; Margaret E. Cook, Royal Free; H. F. G. Corfield, Bristol; F. H. J. Crawford, Liverpool; S. D. de Silva, Ceylon and Univ. Coll.; J. A. Doherty, Durham and Univ. Coll.: W. S. Dyson, Cambridge and Manchester; D. G. Evans, Univ. Coll.; Lena Finkelstein, Charing Cross; F. H. H. Finlaison, R. H. Fish, and E. D. Forster, Cambridge and St. Thomas's; H. R. Fosbery, Middlesex; A. C. Fraser, Cambridge and St. Bart.'s; Lorna M. A. Goulden Bach, Westminster; Mabel E. Grace, Royal Free; C. A. Grant, Cambridge and St. George's; S. R. Gunewardena. Ceylon and Univ. Coll.; G. Hale, Cambridge and St. Thomas's; H. C. Halge, St. Mary's; F. R. T. Hancock, Cambridge and St. Bart.'s; Florence R. Hart, King's Coll.; Eileen E. Harvey, Royal Free; J. Henry, Leeds; A. R. C. Higham, St. George's; F. T. J. Hobday, St. Bart.'s; U. M. Hopkins, Bristol; K. T. Hosain, Punjab; L. H. Howells, London; K. N. Irvine, Oxford and St. Thomas's; O. Ive, Guy's; J. L. S. James, Bristol; G. H. Jennings, Cambridge and St. Mary's; H. B. John, St. Mary's; E. Johnson, Manchester; G. W. Kendrick, St. Thomas's; C. J. King-Turner, Oxford and St. George's; G. C. Knight, St. Bart.'s; J. P. F. Lloyd, Birmingham; A. H. Loudoun, St. Thomas's; H. Lwow, St. George's; D. G. Macdonald, Cambridge and London; A. P. McEldowney, St. Thomas's; Joyce MacInnes, Royal Free; W. McKissock, St. George's; Moyra Macnaughton-Jones, Royal Free; J. D. McVean, Cambridge and Manchester; J. B. Marshall, St. Mary's; C. B. Melville, Melbourne and Middlesex; Blodwen Morgan, Charing Cross; D. K. Mulvany, King's Coll.; Emilata Nawal Kishore, Bombay and Royal Free; Gladys L. Neill, King's Coll.; K. I. Nicholls, Bristol; A. M. Nussbrecher, Middlesex; C. G. Owen, Edinburgh and St. Mary's; R. O. Payne, Guy's; J. H. Pierre, St. Bart.'s; N. S. Plummer, Guy's; E. H. Protheroe Smith, Birmingham; A. Rafla, Cairo; S. Ramadas, Bombay and St. George's; L. Rees, St. Thomas's; Louise Rees, Charing Cross; V. H. Riddell, Cambridge and St. George's; S. L. Rikhye, Lahore; C. G. Roberts, Cambridge and Westminster; D. M. Roberts and B. Rubinsky, London; C. R. Sadler, St. Thomas's; A. R. Sahy, Edinburgh; J. Sakula, Middlesex; L. Seaton, Leeds; T. Shahani, Bombay; Edna F. Sheridan, King's Coll.: H. H. S. Sherwill, Manchester; L. Silman, Leeds; Phyllis F. L. Simon, Royal Free; S. Smith, London; Winifred M. H. Smythe, St. Mary's; G. H. G. Southwell-Sander, R. S. Stacey, and D. J. R. Steen, Cambridge and St. Thomas's; R. W. Stephenson and G. V. Steward, Guy's; J. G. Stewart, Westminster; Enid C. Street, Royal Free; H. M. Strover, Bristol; Mary Sutcliffe, Cambridge and Leeds; A. El K, Talkhan, Cairo; F. H. Taylor, Durham; J. W. P. Thompson, St. Thomas's; O. T. Wade, Leeds; H. Walton, Cambridge and Manchester; E. C. Watson, St. Mary's; J. H. Way, Leeds; Clara E. Wetherall, Royal Free; J. C. G. Whitelaw, Cambridge and St. Thomas's; G. P. B; Whitwell, Guy's; T. C. Williams, Cardiff and Univ. Coll.; T. C. Wilson, Birmingham; and G. R. H. Wrangham and W. Young, St. Mary's.

THE Conservator of the Wellcome Historical Medical Museum (54, Wigmore-street, London, W.1) informs us that "in connection with the anniversary of Galen's birth (A.D. 130) a small exhibition has been prepared" at the Museum.

Royal College of Physicians of Edinburgh.—At a meeting of the College on Feb. 4th, with Sir Norman Walker, the President, in the chair, Dr. Roy Mackenzie Stewart and Dr. William Malcolm McAlister were introduced and took their seats as Fellows. Dr. John Henry Douglas Webster, Dr. Arthur Oliver Gray, Dr. David Pieter Marais, Dr. Sydney Watson Smith, and Dr. James Kirkwood Slater were elected to the Fellowship.

Dr. David Rorie was appointed Dr. Alexander Black Lecturer for 1930.

The College arranged to send a message of congratulation to the Royal College of Physicians and Surgeons of Canada on its erection.

Industrial Health Education Society.—Sir William Haldane will take the chair at the annual meeting of this Society, to be held at the British Medical Association's House in Tavistock-square, London, W.C., at 4 P.M. on Tuesday next, Feb. 18th.

Post-graduate Courses in Berlin.—Besides the regular programme of the post-graduate study a series of special courses will be held in Berlin during March and October. Particulars may be had from the information bureau of the Kaiserin Friedrich-Haus (Berlin N.W.6, Luisenplatz, 2–4), which offers help in procuring suitable lodgings and in arranging attendance at clinics.

Prizes and Grants for Otological Research.—The Council of the Royal Society of Medicine has accepted the sum of £1000 presented by Mr. Norman Gamble for the purpose of providing a prize of £50 every fourth year for original work in otology, the balance of the fund to be used for grants in aid of research. The prize is open to any British subject, whether lay or medical, and applications for the prize and for grants must be received by the Secretary of the Society at 1, Wimpole-street, London, W. 1, not later than Sept. 30th.

1st and 2nd London Sanitary Companies R.A.M.C. (T.F.).—The first reunion dinner, since the end of the late war, of the 1st and 2nd London Sanitary Companies of the Territorial Force was held on Feb. 8th, at the Imperial Hotel. Major Goddard, who commanded the 2nd London Sanitary Company at the outbreak of war, presided over a gathering of more than 300 former officers and men. The guest of the evening was Major-General Sir Wilfred Beveridge, who was the Deputy Director-General, Sanitation, at General Headquarters for the greater part of the war in France, and was therefore the officer responsible for the work of the sanitary sections manned by the two sanitary companies. In responding to the toast of the Guests, Sir Wilfred gave an interesting account of the part played by the sanitary companies in the war. He reminded his hearers that in the original Expeditionary Force no provision was made for sanitary sections, though there was personnel trained in water duties. The two London sanitary companies formed part of the Territorial Force at the commencement of war and had an establishment of six officers and about 150 men in each company. Very soon it was found that there was urgent need in France of men trained in sanitary work, and the sanitary companies were enlarged so as to form a reserve from which officers and men could be sent out to the various theatres of war. The first sanitary section, consisting of one officer and 25 men with full equipment, was sent out in October and was stationed at Rouen. General Beveridge soon found that similiar sections were needed for work with the Divisions, and 12 sections were sent out to France in December from the two sanitary companies and were posted to various Divisions. From this time there was a steady stream of sanitary sections until each Division had its own section, while others were posted on the line of communication. Sanitary sections were also sent to Gallipoli, Italy, Salonica, and Africa. By the end of the war nearly 300 sanitary sections were in being. It was a remarkable tribute to the efficiency of the original companies that it was possible to train such a large personnel of officers and men throughout the whole course of the war. The work of the sanitary section, said Sir Wilfred, was of the utmost value and could not be overpraised. It had been estimated that an army could not afford a wastage from disease and sickness of more than 0·3 per cent. That this figure was rarely reached and scarcely ever exceeded was largely due to the work of the sanitary sections in the field. Major Goddard proposed the health of the Old Comrades of the Sanitary Companies. This toast was responded to by Prof. R. J. S. McDowall, who was in charge of a section during the war. The toast of Absent Comrades was proposed by Major Martin, of the 2nd London Sanitary Company, and responded to by Mr. Manser, a former staff-sergeant, who was chiefly responsible for the arduous task of getting in touch with the former officers and men and for arranging the dinner.

At the quarterly meeting of the directors of the Naval Medical Compassionate Fund on Jan. 22nd, with Surgeon Vice-Admiral Arthur Gaskell in the chair, the sum of £120 was distributed among the several applicants.

Health Conference and Exhibition in Greece.—The first Panhellenic Health Conference will be held in Athens in April and will be followed by an international exhibition of social and individual hygiene from May 1st to July 31st. Exhibits from abroad should arrive before March 31st. The headquarters of the organising committee are in the offices of the Medical Association of Athens, Odos Kriezotou, 1.

Medical Tour in Spain.—A second tour for medical men to the hydromineral and climatic stations of Spain has been arranged for Easter. The party will leave Barcelona by special motor boat on April 13th, visiting Palma (Majorca), Alicante, Malaga, Seville (in time for the celebrated Good Friday procession), and Valencia, returning to Barcelona on April 23rd. There will be an opportunity of seeing the exhibitions at Barcelona and Seville. Further information may be had from Dr. Mañeru, Ronda de Conde Duque, 4, Madrid.

National Council for Mental Hygiene.—A series of lecture-discussions on Mental Health and the Child will be delivered at 11, Chandos-street, Cavendish-square, London, W., on Wednesdays, at 5 P.M. The subjects and lecturers are as follows: The New Psychology and the Parent, by Dr. Hugh Crichton-Miller (Feb. 26th); the Child and the Teacher, by Dr. Letitia Fairfield (March 5th); the Delinquent Child, by Mr. W. Clarke Hall (12th); the Difficult Child at Home and at School, by Dr. William Moodie (19th); Sex Education, by Mrs. Neville-Rolfe (26th); and Choosing a Career, by Dr. R. D. Gillespie (April 2nd). Tickets may be had from the Secretary of the Council, 78, Chandos House, Palmer-street, S.W.1, or at the doors.

Enlargement of Cameron Hospital, West Hartlepool.—The Prince of Wales is being asked to lay the foundation stone of a children's ward to be added to this institution, when he presently visits West Hartlepool. A new radiological block is to be added at the same time.

Tramwaymen and Hospitals.—Of the 8000 tramwaymen in Manchester nearly 6000 are contributing to the local hospitals through a fund started a little over a year ago. Deductions of from 2*d.* to 5*d.* a week are made from their wages, and last year £3201 was thus raised. The contributors and their families are entitled to hospital treatment, and there are no administrative expenses.

Study of Medical Hydrology.—The Committee for the Study of Medical Hydrology in Great Britain informs us that it can arrange for lectures, on medical hydrology and spa treatment, to senior medical students, post-graduate associations, and medical societies. It is also prepared to arrange for visits of such associations to any of the British spas and to give lecture-demonstrations. Further particulars may be had from the hon. secretary, Dr. Geoffrey Holmes, 11, Ripon-road, Harrogate.

The Bath Hospitals.—The Bath Royal United Hospital is to be transferred to Combe Park at a cost of £100,000, in addition to £30,000 to be paid by the corporation for the existing buildings, which it is intended to convert into a technical college. Mr. A. Stanley Wills, of Bath, has given £10,000 towards the amount required.—Lady Stothert has opened two sitting-rooms for the use of patients in the Forbes-Fraser Hospital as a memorial to her husband, the late Sir Percy Stothert, who was chairman of the hospital.

Western Infirmary, Glasgow.—The annual report records an ordinary income of £72,639, and an expenditure which left a deficit of £9665, an improvement upon the £12,337 deficit of the preceding year. There were 15,521 in-patients and 38,437 out-patients, a total increase of 3615. The average period of residence was 18·18 days, as against 20·05 days in 1928, and the average cost per patient was £6 14*s.* 8*d.*, as compared with £7 18*s.* 3*d.* in the preceding year. After deducting patients who died within 48 hours of admission, the death-rate was 5·1 per cent. The means for providing an ophthalmic department have been in hand since 1916, but owing to the continuance of the Rent Restrictions Act it has not been possible to clear the site, which is occupied by tenements belonging to the Infirmary. The new X ray and electrical department is nearing completion, and is expected to be in full working order within the next three months.

BIDEFORD HOSPITAL.—In this small hospital the average cost per occupied bed fell last year from £2 3s. per week to £2 0*s.* 9*d.* Administration cost 3·40 per cent.

BRADFORD HOSPITAL AND CONVALESCENT FUND.—For the sixth successive year this Fund is allocating £20,000 to the City's hospitals and institutions. In the last 25 years £292,000 have thus been provided.

A BRICK HOSPITAL IN THE "GRANITE CITY."—The possibility that the new Joint Hospitals at Foresterhill, may be built of brick instead of the native granite, is causing an animated discussion in Aberdeen. The buildings, instead of costing £400,000 as originally estimated, are now expected to cost half a million at least, and it is understood that the governing body of the Royal Infirmary has therefore been considering the possibility of reducing the amount by building in brick instead of stone. On the one hand, it is argued that every mason in North and East Scotland is already occupied, and that a granite building would progress very slowly owing to the scarcity of labour; on the other hand, bricklayers are said to be even scarcer than masons and men would have to be tempted from England and southern Scotland by the offer of higher wages which would swallow up economies, which, it is represented would, in any event, be very small.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Feb. 18th.—5.30 P.M., GENERAL MEETING OF FELLOWS. Ballot for election to the Fellowship. 8 P.M., PATHOLOGY. Communications: E. R. Cullinan: A Case of Tuberculosis of the Stomach. A. Fleming and I. H. McLean: The Occurrence of Influenza Bacilli in the Mouth. T. H. C. Benians: Treatment of Cases of Acute Osteo-myelitis with Benzol, with the Object of Diminishing the Leucocytosis. W. W. C. Topley: Antibodies in Rabbits. Demonstration: W. G. Barnard: Hæmangeioma of the Cerebrum.

THURSDAY.—5 P.M., DERMATOLOGY. (Cases at 4 P.M.). Dr. H. MacCormac: 1. Morphœa Type of Tuberculide. Dr. H. C. Semon: 2. Leukæmia Cutis. Mr. A. Dickson Wright (introduced by Dr. Graham Little): 3. The Treatment of Varicose Ulcer. Dr. G. B. Dowling: 4. Case for Diagnosis. Dr. W. J. O'Donovan: 5. Poikilodermia of Civatte. Dr. R. T. Brain (for Dr. W. J. O'Donovan): 6. Hodgkin's Disease with Cutaneous Nodules. Other cases will be shown.

FRIDAY.—5 P.M., BALNEOLOGY AND CLIMATOLOGY. Discussion on Bath Reaction in Spa Treatment. Opener: Dr. J. Barnes Burt. 8 P.M., OBSTETRICS, ELECTRO-THERAPEUTICS. Special Discussion on The Position of Radium in the Treatment of Gynæcological Conditions. Openers: Mr. Malcolm Donaldson and Mr. Stanley Dodd, Obstetrics; Dr. A. E. Hayward Pinch and Dr. J. E. A. Lynham, Electro-Therapeutics.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Feb. 17th.—9 P.M., Sir John Thomson-Walker: Enlarged Prostate and Prostatectomy. (First Lettsomian Lecture.)

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, W.

THURSDAY, Feb. 20th.—8.15 P.M., preceded by a Demonstration at 7 45 P.M., Dr. V. B. Wigglesworth: Some Notes on the Physiology of Insects related to Human Disease.

CHELSEA CLINICAL SOCIETY.

TUESDAY, Feb. 18th.—7.30 P.M., Dinner at the Hotel Rembrandt, Thurloe-place, W., followed by a discussion on Defæcation. Dr. Harold Pritchard and Mr. Ivor Back will begin the discussion.

SOCIETY OF MEDICAL OFFICERS OF HEALTH, 1, Upper Montague-street, W.C.

FRIDAY, Feb. 21st.—5 P.M., Dr. R. Veitch Clark, Dr. A. J. Shinnie, and Dr. V. T. Thierens: The Medical Officer of Health in Relation to Housing and Housing Procedure.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Field's, W.C. (Arris and Gale Lectures).

MONDAY, Feb. 17th.—5 P.M., Mr. R. H. O. B. Robinson: The Rôle of Short Circuit Operations in the Treatment of Cholecystitis.

WEDNESDAY.—5 P.M., Mr. W. McAdam Eccles: Anatomy, Orthodox and Heterodox, in Relation to Surgery.

FRIDAY.—Mr. E. R. Flint: The Association Between Gall-bladder Lesions and Hepatitis in the Human Subject.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Feb. 17th to SATURDAY, Feb. 22nd.—MEDICAL SOCIETY, Lecture Room, 11, Chandos-street, Cavendish-square, W., Tues., 4 P.M., Dr. Thomas Tennent: Malaria Treatment of General Paralysis. No fee.—ST. MARY'S HOSPITAL, Paddington, W. Wed., 3 P.M., Dr. C. M. Wilson (Special cases and Out-patients). No fee.—CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C. Wed., 2 P.M. Mr. C. Gill-Carey: Selected Operations on the Ear, Nose, and Throat. No fee.—CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. Special Course in Gynæcology, lectures and demonstrations in the operating theatres. Second week.—HOSPITAL FOR TROPICAL DISEASES, 25, Gordon-street, W.C. Post-graduate course. Tues. and Thurs. afternoons at 2 P.M.—BETHLEM ROYAL HOSPITAL, S.E. Tues. and Sat., 11 A.M., Lecture-demonstrations, Psychological Medicine.—Further particulars from the Fellowship of Medicine.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark Hill, S.E.

THURSDAY, Feb. 20th.—9 P.M., Sir John Thomson-Walker: Enlargement of the Prostate and Its Treatment.

NATIONAL HOSPITAL POST-GRADUATE COURSE, Queen-square, W.C.

MONDAY, Feb. 17th.—12 noon., Dr. Greenfield: Pathology of Nervous System. 2 P.M., Dr. Riddoch: Out-Patient Clinic. 3.30 P.M., Mr. Leslie Paton: The Control of Ocular Movements.

TUESDAY.—2 P.M., Dr. Walshe: Out-Patient Clinic. 3.30 P.M., Dr. Critchley: Central Disorders of Vision.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-Patient Clinic. 3.30 P.M., Mr. Just: Demonstration of Methods of Testing the Eighth Nerve.

FRIDAY.—12 noon, Dr. Purdon Martin: Anatomy and Physiology of Nervous System. 2 P.M., Dr. Adie: Out-Patient Clinic. 3.30 P.M., Mr. Elmquist: Demonstration of Re-educative Exercises.

ROYAL NORTHERN HOSPITAL, Holloway.

WEDNESDAY, Feb. 19th.—3.15 P.M. (at the Royal Chest Hospital), Dr. J. Maxwell: Treatment of Asthma.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

MONDAY, Feb. 17th.—1.30 P.M., The Mouth and Pharynx.

WEDNESDAY.—1.30 P.M., The Larynx.

FRIDAY.—4 P.M., Mr. C. Gill-Carey: Foreign Bodies in the Food and Air Passages.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James' Hospital, Ouseley-road, Balham, S.W.

WEDNESDAY, Feb. 19th.—4 P.M., Dr. Arthur H. Douthwaite: The Treatment of Osteo-Arthritis and Rheumatoid Arthritis.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Feb. 17th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose, and Throat Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat and Ear Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases. Clinics. Operations.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck-street, W.

THURSDAY, Feb. 20th.—8.30 P.M. (in the Reid-Knox Memorial Hall of the Institute), Dr. A. E. Barclay: Mechanism of Swallowing. Mr. J. Preston Maxwell: Osteomalacia and Fœtal Rickets. Dr. John Muir: The Irritable Colon.

FRIDAY.—4 P.M., Medical Committee. Reports on cases of gastro-intestinal conditions are especially requested for this meeting, but other cases of interest will also be welcome.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Feb. 18th.—5 P.M., Dr. G. B. Dowling: Staphylococcal Infections.

THURSDAY.—5 P.M., Dr. I. Muende: Pathology Demonstration.

ST. MARY'S HOSPITALS, Manchester.

FRIDAY, Feb. 21st.—4.15 P.M. (at the Whitworth-street West Branch), Post-graduate Lecture, Dr. D. Dougal: Genital Prolapse.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

TUESDAY, Feb. 18th.—3.30 P.M. (at the Jessop Hospital), Mr. Chisholm: Consideration of the Report of Departmental Council on Training and Employment of Midwives.

FRIDAY.—3.30 (at the Royal Infirmary), Mr. E. F. Finch: Renal Tumours.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

WEDNESDAY, Feb. 19th.—4.15 P.M. (at the Royal Maternity and Women's Hospital), Prof. J. H. Munro Kerr: Obstetrical Cases.

Appointments.

Lawrie, J. H. D., M.D. Edin., D.P.H., has been appointed Medical Officer of Health for Macclesfield.

Logan, J. S., M.B., Ch.B.Liverp., Deputy Medical Officer of Health for Swindon.

Essex County Hospital, Colchester: **Wirth**, M.D. Malta, Hon. Surgeon, and **Reid**, M.B., Ch.B. Aberd., Hon. Asst. Surgeon.

Certifying Surgeons under the Factory and Workshop Acts: **Hilton**, M. J., M.B., M.S.Durh. (Camberwell); and **O'Donnell**, G. P., M.B., B.Ch. N.U.I. (Redruth).

Vacancies.

For further information refer to the advertisement columns.

Abergele Sanatorium, North Wales.—Temporary Med. Supt. 15 gns. a week.
Accrington, Victoria Hospital.—H.S. £150.
Bath, Royal United Hospital.—H.S. At rate of £150.
Bedford County Hospital.—H.S. At rate of £175.
Birkenhead General Hospital.—Sen. H.S. and H.P. At rate of £150 and £100 respectively.
Birmingham City and University, Joint Board of Research for Mental Disease.—Histological Asst. £4 weekly.
Birmingham General Hospital.—H.P. and H.S. Each £70.
Birmingham University.—Asst. Lecturer and Demonstrator in Anatomy. £300.
Bootle Borough Hospital.—Hon. Laryngologist and Aurist.
Bradford Royal Eye and Ear Hospital.—Jun. H.S. £150.
Bradford, St. Luke's Municipal General Hospital.—H.P.'s. and H.S.'s. Each at rate of £200.
British Red Cross Society, Clinic for Rheumatism, Regent's Park.—Clin. Pathologist (part-time). £250.
Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.
Cardiff Royal Infirmary.—H.S. to Ophth. Dept. At rate of £75.
Carlisle, Cumberland Infirmary.—H.P. Also H.S. to Special Depts. Each at rate of £155. Also H.S. At rate of £175.
Carlisle, Cumberland and Westmorland Mental Hospital.—Deputy Med. Supt. £500.
Charing Cross Hospital, W.C.—Med. Reg. £150. Obst. Reg. £100. Also Registrar to Ear, Nose, and Throat Dept. £100.
Chester Royal Infirmary.—H.S. £150.
Chiswick Hospital, The Mall, Chiswick.—Hon. Deputy Anæsthetist.
Dartford, Kent, Darenth Training Colony.—Med. Supt. £1000.
Derby, Derbyshire Education Committee.—Asst. School M.O. £600.
Dewsbury County Borough.—Deputy School M.O., &c. £600.
Doncaster Royal Infirmary.—Third H.S. At rate of £150.
Dreadnought Hospital, Greenwich.—Phys.-in-charge of Out-Patients.
Durham C.C.—Deputy County M.O.H. £1000.
East Ham Memorial Hospital, Shrewsbury-road, E.—Hon. Asst. Ophth. S. Also Res. M.O. At rate of £200.
Evelina Hospital for Children, Southwark, S.E.—Hon. Surgeon to Out-patients.
Gloucester County and City Mental Hospitals.—Med. Supt. £1100.
Golden-square Throat, Nose, and Ear Hospital.—H.S. £100.
Gravesend and North Kent Hospital.—Jun. H.S. £100.
Great Yarmouth General Hospital.—Sen. H.S. £150.
Halifax Corporation Isolation Hospital.—Res. M.O. £350.
Hertford County Hospital.—Res. Surg. O. At rate of £250.
Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each at rate of £100.
Hull Royal Infirmary.—Cas. H.S. At rate of £130.
Ipswich, East Suffolk and Ipswich Hospital.—Cas. O. £150.
Kent County Council.—Asst. M.O., &c. £600.
Kent Education Committee.—Dental Surgeon. £500.
Larbert, Stirling District Mental Hospital.—Jun. Asst. M.O. £300.
Leicester, City Mental Hospital, Humberstone.—Third Asst. M.O., &c. £500.
Leicester Royal Infirmary.—H.S.'s. and H.P.'s. Each at rate of £125.
Liverpool, Royal Babies Hospital, Woolton.—Res. M.O. At rate of £90.
Liverpool Stanley Hospital.—H.P., Two H.S.'s, and Gynæcological H.S. Each at rate of £100.
Macclesfield General Hospital.—Second H.S. At rate of £150.
Maidstone, Kent County Ophthalmic and Aural Hospital.—H.S. to Ear, Nose and Throat Dept. At rate of £200.
Manchester and Salford Hospital for Skin Diseases.—H.S. £100.
Manchester City.—M.O. for Maternity and Child Welfare. £600.
National Hospital for Diseases of the Heart, Westmoreland-street, W.—Res. M.O. At rate of £150.
Northern Rhodesia, Roan Antelope Copper Mines, Ltd.—Jun. M.O. £900–£1000.
Oswestry, Shropshire Orthopædic Hospital and Agnes Hunt Hospital.—H.S. At rate of £200.
Plymouth City Mental Hospital, Blackadon, Ivybridge.—Med. Supt. £750.
Plymouth Royal Eye Infirmary.—Hon. Surg.
Portsmouth, St. Mary's Hospital, Institution and Children's Home.—Third Asst. Res. M.O. £250.
Preston and County of Lancaster Royal Infirmary.—H.S. £150.
Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Asst. Res. M.O., Res. Anæsthetist. Also Dist. Res. M.O. At rate of £80.
Richmond, Surrey, Royal Hospital.—Jun. H.S. At rate of £100.
Royal National Orthopædic Hospital, Great Portland-street, W.—H.S. At rate of £150.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—H.P. At rate of £100.
St. John's Hospital, St. John's Hill, Wandsworth, S.W.—Second Asst. Res. M.O. £400.
St. John's Hospital for Diseases of the Skin, 49, Leicester-square, W.C.—Sen. and Jun. Hon. Med. Registrars.
St. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C.—H.S. At rate of £75.
Salford Royal Hospital.—H.S. to Orthopædic Dept. At rate of £125.
Sheffield, Jessop Hospital for Women.—Asst. H.S. At rate of £100.
Sheffield Royal Infirmary.—Asst. Cas. O. At rate of £80.
Stafford, Staffordshire General Infirmary.—H.S. and H.P. At rate of £200 and £150 respectively.
Taunton and Somerset Hospital.—Jun. House M.O. At rate of £100.
Tiverton Hospital, Devon.—H.S. At rate of £100.
Truro, Royal Cornwall Infirmary.—H.S. £170.
West Bromwich and District General Hospital.—H.S., H.P., and Cas. H.S. Each at rate of £200.
West London Hospital, Hammersmith-road, W.—H.P., Two H.S.'s and Res. Anæsthetist. Each at rate of £100.
West Middlesex Hospital, Isleworth.—Asst. M.O. At rate of £250.
Western Ophthalmic Hospital, Marylebone-road, N.W.—Four Chief Clin. Assts. Each 1 gn. per session.
Willesden U.D.C.—Asst. M.O. £600.
York City Hospitals, Maternity Hospital and Sanatorium.—Res M.O. £350.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Bodmin (Cornwall), and Ross (Hereford).

The Home Secretary gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act for the Districts of the Kingsbridge, Plymouth, and Totnes County Courts. Applications for the post should reach the Private Secretary, Home Office, Whitehall, S.W., not later than March 8th.

The Home Secretary invites applications for the post of Medical Referee under the Workmen's Compensation Act, to deal with cases arising in the districts of the Chard, Langport, Taunton, Wellington, and Williton County Courts (Circuit No. 57). Applications should reach the Private Secretary, Home Office, Whitehall, London, not later than March 1st.

The Home Secretary also gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act, for Midlothian County (Sheriffdom of the Lothians and Peebles. Applications should reach the Private Secretary, Scottish Office, Whitehall, London, not later than March 3rd.

Births, Marriages, and Deaths.

BIRTHS.

Aymer.—On Feb. 8th, at Oakwood-court, Kensington, the wife of Dr. Aymer, of Holmwood, St. John's-road, Boscombe, Hants, of a daughter.

DEATHS.

Apperly.—On Feb. 7th, at The Dower House, Gerrards Cross, Bucks, Ebenezer Apperly, L.D.S. R.C.S. (Eng.), in his 86th year.

Green.—On Feb. 5th, at Queen Alexandra's Military Hospital, Millbank, S.W., Major-General Sebert Francis St. Davids Green, C.B., C.B.E., M.D. (late R.A.M.C.), aged 62.

Hempson.—On Feb. 6th, at Tunbridge Wells, William Ernest Hempson, aged 71.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

INDEX TO "THE LANCET,"

VOL. II., 1929.

The Index and Title-page to Vol. II., 1929, which was completed with the issue of Dec. 28th, is now ready. A copy will be sent gratis to subscribers on receipt of a postcard addressed to the Manager of The Lancet, 7, Adam-street, Adelphi, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

Notes, Comments, and Abstracts.

ALEXANDRA DAY.

Alexandra Rose Day this year is to be June 24th for London and any place within 50 miles. Other places can choose for the celebration any day they wish after arrangement with the Rose Day authorities. It is a curious fact that this charitable institution is not even more widely supported than it is, for it is one of the best and most economically managed of all similar efforts. The organisation takes 5 per cent. of what is collected, the rest going to the charities. These are not necessarily hospitals, but any charity for aiding the sick, the allocation being in the hands of the local organisers. The roses are all made by crippled children, and are, of course, supplied by the Rose Day Organisation, as is all necessary information and propaganda. These can be obtained from the Organiser, Miss Mary Beeman, 33, The Boltons, London, S.W.10.

Many hospitals in the provinces do not avail themselves of the Rose Day opportunities, and this seems a pity, both from their own point of view and from that of the Rose Day organisation; for the latter, successful though it already is, is still anxious to extend the field which it has covered during the last 19 years. At first it was purely a London affair, but now it embraces the provinces as well as places abroad, and it has since its inception distributed more than one and a quarter million pounds in aid of hospitals and institutions which care for the sick. We believe that those bodies which are not yet affiliated to the Alexandra Rose Day Fund, and which are eligible so to be, would find that any trouble involved in taking part in the Rose Day collection would repay them handsomely.

HEALTH WORK OF THE LEAGUE OF NATIONS

A SURVEY OF TEN YEARS.

THE last chapter of Mr. John Eppstein's attractive History of the Origins of the League and of its Development from A.D. 1919 to 1929 (London: Mayfair Press, 7s. 6d.) contains an account of the social services of the League which, as Mr. Bernard Shaw has said, would justify its existence ten times over. Mr. Eppstein tells us how the call came to the League from Eastern Europe before any permanent health section had been established at Geneva. The danger was so urgent along a line from the Baltic to the Black Sea that only the combined Governments of Europe could possibly provide assistance on the needful scale. It was to face this threatening crisis that the League Covenant authorised the appointment of a health organisation under which Dr. Norman White set up a chain of hospitals and quarantine stations which saved the rest of Europe from pestilence. The situation was reviewed by the Warsaw Health Conference in 1922, shortly after which the movement of Greek refugees gave rise again to the fear of a spread of cholera, small-pox, typhoid, typhus, and dysentery throughout Western Europe. Moved by these events, the Third Assembly of the League in 1923 gave a definite constitution to the Health Organisation with a standing committee of 16 members, and Dr. Rajchmann the first director. Two years later the Epidemiological Bureau was established at Singapore to which all outbreaks of fever in the Far East were to be reported, something like 150 ports being brought into constant touch with the central station. What has followed since is common knowledge, but it may be noted with interest that Bolivia, as her first act on returning to the League after a long absence from Geneva, requested the assistance of the League in reorganising her public health service.

PUBLIC HEALTH IN IRAQ.

THE latest report on the administration of Iraq, issued by the Colonial Office, shows that 24 hospitals and 78 dispensaries are maintained. The total number of beds in the hospitals is 1205, but it is stated that while the accommodation is generally adequate for the immediate requirements of most provinces, that in Baghdad and Mosul remains unsatisfactory. Serious cases are turned away daily in both places, particularly in Baghdad, where the average duration of stay of patients in hospital is still not more than 11 days. The Government, however, has under consideration a scheme for increasing the beds for free patients at the Royal Hospital, Baghdad, from 250 to 500, and for rebuilding the specialist institutions situated in that hospital. As regards Mosul, a new hospital of 220 beds has been included in the building programme of the Government for 1929. The new Maude Memorial Out-patient Department at the Royal Hospital, Baghdad, new hospital buildings at Diwaniya and Amara, the Royal Iraq College of Medicine, and a new mortuary and operating theatre at the Royal Hospital were all nearing completion at the end of the year. The total number of in-patients and of out-patients treated in health service institutions showed the increase over those treated in 1927 and even over those treated in 1926, which was an epidemic year for malaria in Iraq. There were no epidemics of general ailments such as malaria or influenza during 1928, and the statistics may therefore be taken as showing a very definite increase in the normal work of the Health Service. The work of charitable institutions is a very small factor in the problem of the medical treatment of the population. Of the 1035 cases treated during the year in such institutions, 1011 were admissions to the Meer Elias Hospital, which is a Jewish infirmary, and to the Rima Khedoury Eye Hospital, another Jewish institution, both in Baghdad. Iraq is unfortunate, in comparison with most other countries, in having so little assistance from voluntary sources in the field of medical work. The Anglo-Persian Oil Company at Khanaqin and the Turkish Petroleum Company in the Kirkup province maintain their own doctors and hospitals for the treatment of their employees. Their dispensaries also freely treat the country people near the oilfields.

There is still difficulty in finding Iraqi doctors to fill posts in out-stations, and this will continue for a few years, but the establishment of the medical school has removed anxiety for the future. There is also a shortage of other trained medical personnel, such as pharmacists, dressers, and nurses, which causes great difficulty in the establishment of new dispensaries and in the development of existing health institutions. This results from the strict economy enforced upon the Health Service, which has made it impossible to entertain in its large institutions surplus personnel under training for future requirements.

The number of births registered in Baghdad (with a probable population of 250,000) in 1928 was 5167; in Basra (80,000) 980; and in Mosul (80,000), 2763. The deaths registered in the same period were in Baghdad 6396, in Basra 1670, and in Mosul 2686. In the absence, however, of reliable census figures it is impossible to calculate birth- and death-rates with any statistical value for these towns. The percentage of deaths under one year was in Baghdad 30·7, in Basra 26·3, and in Mosul 39·9. Maternity and child welfare work is being gradually developed in the large towns.

SUPPLY OF OFFICERS FOR THE R.A.M.C.

A CORRESPONDENT writes: On looking through some old files of *Punch*, I came across the enclosed, which may interest you. Apparently the Army had some difficulty in obtaining medical officers at that period, 54 years ago.

Dearth of Army Doctors.—The papers report a grievous lack of candidates for the Commission of Medical Officers in the Army. Private practice is lucrative to few but the most eminent Physicians and Surgeons. Anything like adequate pay and position on a firm footing with Combatant Officers surely might be expected to attract at least a sufficiency of Army Surgeons. These attractions have yet to be tried. (Feb. 19th, 1876.)

UTOPIAS.

THOSE who like guessing about the future of a world in which man is the only live thing whose existence is recognised may find some interest in two small books[1]; but they are mostly idle and narrow speculation. Mr. Bernal imagines that a human of the nature of a robot really will make himself a happy home beyond the bright blue skies (spherical in shape) where he will subdue his passions and stupidities. Mr. Hatfield proposes a mechanised state in which no one need think; he seems to say little more than that the process whereby the hard lessons of experience have become instinctive reactions will continue in the future as it has in the past. Neither of their visions bears the stamp of authentic prophecy.

EHRLICH'S ALDEHYDE REACTION.

THE reagent used in this test for urobilin and urobilinogen is a 3 per cent. solution of paradimethylaminobenzaldehyde in 50 per cent. hydrochloric acid. Our attention has been called to an erroneous extra syllable "azo" which has inadvertently slipped into the name of the reagent as given on p. 10 of THE LANCET Extra Number No. 1 on Modern Methods in Abnormal and Difficult Labour. The writer was there following a similar slip in an earlier edition of Beaumont and Dodds's "Recent Advances in Medicine."

A BLOOD-SUGAR CHART.

Messrs. H. K. Lewis and Co. have sent us a specimen of a blood-sugar chart for recording sugar tolerance. The average normal percentages after ingestion of 50 g. of glucose are set out in red at intervals of 30 minutes, on which the clinician superposes in black the values which he obtains in a particular case. The charts are priced at 6s. per 100 or 50s. a thousand.

Hunterian Oration

ON

HERO WORSHIP IN SURGERY.

Delivered in the Royal College of Surgeons on Feb. 14th, 1930,

BY ERNEST W. HEY GROVES, F.R.C.S.,

PROFESSOR OF SURGERY IN THE UNIVERSITY OF BRISTOL.

"One comfort is, that Great Men, taken up in any way, are profitable company. We cannot look, however imperfectly, upon a great man, without gaining something by him"—*Carlyle, "Hero Worship."*

MY LORD, LADIES AND GENTLEMEN,—We have met to-day on the birthday festival of John Hunter, one of the greatest heroes of English surgery.

Considerably more than a century has elapsed since in 1814 this Oration was founded by Hunter's executors, Dr. Matthew Baillie and Sir Everard Home, "in honour of surgery and in memory of men by whose labours it has been advanced."

In pursuance of this bequest the Oration has now been delivered 75 times, 38 of which have been in the present theatre. Of these, 68 have been published and are now in our library. It would be presumptuous on the part of the present speaker to utter one word without having first read all these published orations. They now cover a sufficient period of time (1814 to 1928), and that a period of the greatest growth and activity in surgery, to make their perusal one of great interest and instruction, especially in marking notable landmarks in the history of surgery and this College.

NOTES OF THE PREVIOUS ORATIONS.

EVERARD HOME, *1814*.—Wiseman as founder of surgery in 1600. Emancipation of surgery from medicine. Knowledge of anatomy chief advance in surgery. Cheseldon: anatomy, lithotomy. Pott, Hunter: anatomy. General principles of animal life. The importance of experiment.

SIR WILLIAM BLIZZARD, F.R.S., *1815*, Surgeon to the London Hospital.—General reflections on surgery and its relation to anatomy. Harrison: first surgeon and founder of London Hospital. Belchier, Sharpe, Hawkins, Cheseldon, Pott, Bromfield, Warner, Thomson. Compare Newton with Hunter. Relation of life to matter.

HENRY CLINE, *1816*.—Not published.

WILLIAM NORRIS, *1817*, Master of the College, Surgeon to Charterhouse and Magdalen Hospital.—Early teachers: Hippocrates, Celsus. John Arden, Leader of surgery during the Renaissance. Traces beginning of improvement in modern surgery to the regular teaching of anatomy. William Hunter, Percival Pott: "In London there are seven large Hospitals." Life work of John Hunter. His Museum.

SIR DAVID DUNDAS, Bt., *1818*, Sjt. Surgeon to H.M. King George III.—Ancient teachers. First effect of firearms. Appearance of venereal disease. Paré: use of ligatures instead of caustics or cautery. Wiseman, Cheseldon, Pott. Hunter on gunshot wounds—not necessary to enlarge such wounds without special reason. Work about popliteal aneurism. Hunter's doctrines of the nature of life. Eulogy on George the Third in relation to encouragement to science and surgery. Obituary notice of Sir James Earle. Improvements in extracting cataract and in treating hydrocele. "If at any former time surgeons . . . allowed themselves to be under the control of physicians that is not likely to happen again."

JOHN ABERNETHY, F.R.S., *1819*, Surgeon to St. Bartholomew's Hospital.—The nature of surgery. Early history of surgery. Rise of the Barber surgeons. Haller's work as a physiologist. Plea for greater facilities for getting bodies for dissection; also for post-mortem examinations. "Those who far precede others must necessarily remain alone." "His disposition to distrust opinions and to examine every subject for himself." Eulogy of Hunter's character and benevolence.

ANTHONY CARLISLE, F.R.S., *1820*, Surgeon to Westminster Hospital, Surgeon Extraordinary to H.M. George IV.—Obituary notice of Will Hey. A very eloquent—rather pompous—eulogy of Hunter, but going out of the way to point out his lack of learning, of languages and science.

THOMAS CHEVALIER, F.R.S., *1821*, Surgeon Extraordinary to King George IV., Professor of Surgery and Anatomy to the College.—History of Surgery, life and work of Hunter. Refers to treatment of chronic ulcer of the leg, and to Underwood, Bayntum, Sir Joseph Banks, Cuvier.

SIR EVERARD HOME, Bt., P.R.C.S., *1822*, Senior Surgeon to St. George's Hospital.—Refers to granting by George the Fourth of new Charter and the raising of the College to the status of a Royal College. Account of life and works of Sir Joseph Banks, who accompanied Captain Cook round the world (Vice-President of Royal Society).

SIR WM. BLIZZARD, P.R.C.S., *1823*, Surgeon to the London Hospital.—Preface repudiates fear that the subjects for Hunter's Oration would soon be exhausted! Deplores the prevalence of practice by unqualified surgeons. Sir Joseph Banks, Sir Charles Blicke, Sir James Earle, Mr. Long, Mr. Keate, Mr. James Wilson, Mr. Chandler, Mr. Hey, Dr. Jenner. "The Council of this College are unshaken in their confidence in the efficacy of vaccination."

HENRY CLINE, *1824*.—Not published.

WILLIAM NORRIS, P.R.C.S., *1825*, Surgeon to Charterhouse and Magdalen Hospitals.—On medical education. The Hunterian Collection.

SIR ANTHONY CARLISLE, F.R.S., *1826*, Surgeon to H.M. King George IV. and to Westminster Hospital.—Arguments in favour of study of zootomy and animal anatomy. Description of the oyster and discussion on the formation of shell, teeth, and bones.

H. LEIGH THOMAS, F.R.S., *1827*.—Life and work of Cruikshank, his anatomical researches. Of Hunter he says: "The calibre of whose capacious mind, not being circumscribed by devotion to received opinions, studied solely the book of Nature."

SIR WM. BLIZZARD, *1828*, Senior Surgeon to the London Hospital.—Again deplores the practice of unqualified surgery. He argues against the establishment of special military and also of ophthalmic hospitals. Obituary of Shaw, Harkness, Wm. Norris.

JOHN VINCENT, *1829*, Surgeon to St. Bartholomew's Hospital.—"The measure of excellence in man is discovered in his aptitude to be governed by the power of truth." "One of the most powerful influences that retard the advancement of science is opinion. Opinion is the admission of a proposition without proof." Obituary notices of Heaviside, Macgregor, and Long.

GEORGE JAMES GUTHRIE, *1830*.—Not published.

ANTHONY WHITE, *1831*.—Not published.

SAMUEL COOPER, *1832*, Professor of Surgery to the University of London, Surgeon to the Bloomsbury Dispensary.—"The noble and opulent—as the patrons and dupes of murderous quackery." Appreciation of Hunter. Historical retrospect. Obituary of John Abernethy and Headington.

JOHN HOWSHIP, *1833*, Surgeon to St. George's Infirmary.—Historical retrospect. Comments on Hunter's Museum. Obituary notices of Abernethy, Sir Everard Home, and Baron Cuvier.

SIR WILLIAM LAWRENCE, F.R.S., *1834*, Surgeon to St. Bartholomew's Hospital.—History of Hunter. Adverse criticism of his work on venereal disease. Refers to Museum, Hunter's specimens 7833.* Additions 3951. Refers to the distribution of his MSS. and to Abernethy and Cuvier.

1835 and *1836*.—No Orations.

SIR BENJAMIN BRODIE, Bt., F.R.S., *1837*, Sjt. Surgeon to the King, Surgeon to St. George's Hospital.—Regards treatise on blood and inflammation as Hunter's most important work. First instance of inductive method of philosophy applied to pathological science. "He loved knowledge for its own sake." Obituary notices of Sir Everard Home, Sir W. Blizzard. Refers to the completion of the new building.

BENJAMIN TRAVERS, F.R.S., *1838*, Surgeon Extraordinary to H.M. the Queen, Surgeon to St. Thomas's Hospital.—Hunterian eulogy. Obituary of Henry Earle. "If to have lived in advance of the time be, as has been said, the truest test of genius, let Hunter be tried by this standard."

EDWARD STANLEY, F.R.S., *1839*, St. Bartholomew's Hospital.—"The successful treatment of aneurism, to be reckoned the fairest of the fruits of Hunter's genius." Refers to Hunter's first and third cases who lived 40 years after the operation. Later surgical advances. Lithotrity, tenotomy for congenital deformities. Treatment of fractures by apparatus, which fixed the fracture but allowed movement of the limb. Thomas Blizzard and Swan.

JOSEPH HENRY GREEN, F.R.S., *1840*, Surgeon to St. Thomas's Hospital.—Obituary notice of Henry Coleman. Discourse on medical philosophy. Bacon's deductive logic. Hunter's vital dynamics. "He brought the whole art of healing into immediate connexion with the speculative sciences of Nature." Evolution of the idea of power. Transcendental anatomy. Gradation of animal life. Characteristics of man's bodily frame. Hunter's pathology. Ideas of instinct.

Thomas Callaway, *1841*.—Not published.

G. C. Babington, *1842*, Surgeon to St. George's Hospital.—Obituary of Sir Astley Cooper. "John Hunter's discoveries are great in themselves; but their true value is to be found in the number of other discoveries to which they have given birth." Hunter as an exponent of the Baconian philosophy.

James Arnott, *1843*, Surgeon to the Middlesex Hospital.—Obituary notice of Sir Charles Bell, his work on the nervous system. Lairey who instituted mobile ambulances and rose with the rise of Napoleon. Hunter's Museum. Work on Aneurism, refers to 389 cases with 277 successes.

John F. South, *1844*.—Not published.

1845.—No Oration.

Sir William Lawrence, F.R.S., *1846*, Surgeon Extraordinary to the Queen, Surgeon to St. Bartholomew's Hospital.—Refers to Jenner's discovery as arising out of his education by Hunter. Hunter's specimens numbered 10,563,* and to these had been added 12,347. Refers to Mr. Paget being appointed to write the catalogue of the pathological specimens. Foundation and origin of the Royal College of Surgeons; the Museum and Library. Heated defence of the policy of the R.C. of Surgeons and criticism of the suggested "Royal College of General Practitioners."

Joseph Henry Green, *1847*, Surgeon to St. Thomas's Hospital.—Refers to the recent institution of the Fellowship. The foundation of a liberal education. Language, literature, mathematics, natural history. The cultivation of scientific insight. Value of a University education.

Richard Grainger, F.R.S., *1848*, Surgeon to St. Thomas's Hospital.—The recent scientific advance of anatomy and physiology. Embryology: development of the mammalian ovum. The dependence of function on structure. Microscopical anatomy. The nature of secretion. Physiology based on physics and chemistry. Obituary notices of Liston and Morgan.

Cæsar H. Hawkins, *1849*, Surgeon to St. George's Hospital (Prince Albert present).—States that the pathological specimens in the Museum had doubled in number. Library contained 23,000 volumes. Obituary notices of Briggs, Callaway, Samuel Cooper. Progress in physiology—excretion and secretion. Humoral pathology. Discovery of anæsthesia. Notes increasing international coöperation in science, but suggests that there is urgent need for similar coöperation in regard to experience and statistics among hospitals.

Frederick C. Skey, F.R.S., *1850*, St. Bartholomew's Hospital.—Obituary of Clift who had preserved the Hunterian Collection until it was taken over by the R.C. of Surgeons. Also of Key, Andrews, Morton (Newcastle), Pennington. "The profession of medicine is at the present day a degenerate pursuit." Want of education, ignorance of classics and of science. Urges the need of preliminary education. Deplores the system of apprenticeship. "The degenerate standard of medical ethics." "The law only allows the doctor to be remunerated for selling physic."

R. A. Stafford, *1851*.—Printed but not delivered. Jenner, Dr. Baillie, Abernethy, Astley Cooper, Clift, Samuel Cooper, Charles Bell, Earle.

James Luke, *1852*, Senior Surgeon to the London Hospital.—Obituary of Vincent. Importance of education. Hunter's philosophy and his Museum.

Bransby Cooper, F.R.S., *1853*, Surgeon to Guy's Hospital.—Describes Hunter's work, illustrated by specimens from the Museum. Obituary notices of Vincent, Dalrymple, Pereira, Sir Charles Forbes, Sir John Webb, Lawrence, and Dr. Mantell. The first occasion when the Oration was given in the present theatre.

1854.—No Oration.

Joseph Hodgson, F.R.S., *1855*.—Examination of Hunter's teaching. "The founder of scientific physiology." An appreciation of Jenner who saved 80,000 lives each year.

Thomas Wormald, *1858*.—Hunter's work on inflammation of veins and in curing aneurism. Mentions that Prof. Owen had left the R.C. and S. for the British Museum.

John Bishop, *1859*, Surgeon to the Northern Dispensary.—Museum contained 45,000 preparations, of which 14,000 were microscopic. Obituary notices of Keate, Travers. Improvements in microscope. Pathology of inflammation. Work of Virchow and Lister. Ollier's work on the periosteum. New Medical Act. Advances in physiology, chiefly in relation to the nervous system.

William Coulson, *1861*.—Refers to the fact that Hunter's remains had been transferred to Westminster Abbey. "As he had laid the foundation of scientific surgery so did he found what I venture to term physiological pathology."

George Gulliver, F.R.S., *1863*.—Hunter's ideas of the blood. Doctrine of fibrin and its nature. Obituary notices of Quekett, Norman, Stanley, Brodie, Hewson.

1865.—Not published.

John Hilton, F.R.S., *1867*, Surgeon to Guy's Hospital.—Chiefly a discussion of Hunter's doctrines of sympathy (one diagram from Hunter).

Richard Quain, F.R.S. and P.R.C.S., *1869*.—Hunter and his Museum. *Arrest of medical progress in dark ages* ascribed to the abuse of authority in education. Criticism of English school and University education. Folly of *spending most time on dead languages*. Plea for good teaching of English language and of natural science.

Sir Wm. Fergusson, P.R.C.S., F.R.S., *1871*, Surgeon to the Queen.—Hunter's life and Museum. Four illustrations of grafting. Hunter's experiments on spurs and teeth grafted on cock's comb. Obituary notices of Wardrop, Sir W. Lawrence, Hodgson, Sir James Simpson, James Syme.

Henry Hancock, *1873*, Surgeon to Charing Cross Hospital.—Obituary notice of Skey, Sir James Palmer, Sir John Fife, Solly, Parker, Kempe, Delagrade, Carden, Poland, Coote. Considers that the lack of education was no bar to Hunter's progress. Recites the many men of genius who have been in like circumstances. Criticises the examination system. Thinks it would have kept Hunter out.

Le Gros Clark, F.R.S., *1875*, Surgeon to St. Thomas's Hospital.—Obituary notices of Partridge, Jordan, Bishop, Cutcliffe, Turner, Wormald, Wyatt, Cutler, Swan, Martin, Kiernan. Refers to proposed coöperation with Royal College of Physicians for Conjoint examination. Conservative tendency of surgery. Importance of rest. Water more useful than drugs. Excision of joints. Excision of cancer. "I feel persuaded that the antidote to this malignant disease must be sought in therapeutics and hygienic measures." Deplores that the printing and illustrating of books substitutes reading for dissection and clinical observation. "A love of truth was the mystic altar before which he ever knelt, the energising impulse which determined and regulated his every aim and purpose, the guiding star of his existence."

Sir James Paget, *1877*, Surgeon to St. Bartholomew's Hospital (before the Prince of Wales).—"The happiness of intellect is in its work." "The desire for knowledge, both for its own sake and for the happiness of gaining it and using it became like an insatiable passion." "For Hunter's true thoughts still live in us and they will live after us and never cease to help and urge men onward in the pursuit of truth." "In the world of mind he that is mortal may produce that which is immortal." Obituary notice of Sir Wm. Fergusson.

George Murray Humphry, *1879* (Cambridge).—Two salient, all-pervading features, which may be expressed by the words "work" and "thought," or "observation" and "reflection." First mention of antiseptic treatment of wounds. Spencer Wells and Keith's establishment of ovariotomy. The urgent need of experimental research. The difficulties raised by opponents of experiment. True principles of teaching should be to give facts which lead to and establish principles. Growth of knowledge—danger of cramming. Danger of examinations. Obituary notice of John Hilton, George Firth.

Luther Holden, *1881*, Surgeon to St. Bartholomew's Hospital.—Throws doubt on the alleged lack of education. Thinks Hunter was at school and then at Glasgow University, and studying with Cullen before he went to London. Tribute to Hunter as an anatomist, comparative anatomist, physiologist, and pathologist. Plea for classic education. Obituary notice of Henry Hancock, Callender.

Spencer Wells, P.R.C.S., *1883*.—Obituary notices of Luke, South, Gulliver, George Crichett (progress in ophthalmology). Joseph Clover (anæsthesia), and many others less known. Progress in military and naval surgery. Transport of wounded. Advantages of anæsthetics and antiseptics. Progress of abdominal surgery. Deplores the difficulties and restrictions placed in the way of experiments. First reference to bacteria. Cheyne visiting Koch and working on tubercle. Work of Pasteur and Devine on microbes. "We support the law which protects the many from the danger to which a few ignorant opponents of compulsory vaccination would expose the whole population." Thirty diseases in man and animals proved to depend upon specific microbes.

JOHN MARSHALL, F.R.S., *1885*, Surgeon to University Hospital.—Obituary notices of Allen Thomson, Cæsar Hawkins, Erasmus Wilson. After a sketch of John Hunter's life he attempts to estimate his opinion in regard to modern developments. Would resent restrictions on experiment. Was on the same idea as Darwin. Variation in species and stages of embryo showing same changes as in race. Anæsthetics and antiseptics.

WILLIAM S. SAVORY, F.R.S., *1887*, Surgeon to St. Bartholomew's Hospital.—The philosopher of surgery. The idea of the unity of design. "He effected more by the nature of the questions which he set than by the answers which he worked out." "Is not surgery itself then as a science in danger from the extension of surgery as an art?"

HENRY POWER, *1889*, Surgeon to St. Bartholomew's Hospital.—Hunter as a physiologist and experimenter. The value and results of recent physiological experiments. "The experiment and researches of Sir J. Lister." The new rooms devoted to research.

JONATHAN HUTCHINSON, F.R.S., *1891*, Surgeon to the London Hospital.—Obituary notices of Matthews Duncan, John Marshall. Claim for reference to mother in tracing character. Great estimate as a naturalist and philosopher. Poor opinion of his writings on venereal disease. Considers that knowledge of geology shown in his catalogue of fossils as very remarkable as being before his time.

THOMAS BRYANT, *1893*, Surgeon to Guy's Hospital (given before H.R.H. the Prince of Wales and H.R.H. the Duke of York).—Obituary notices of Prescott Hewitt, John Wood, Berkely Hill, Sir Wm. Bowman, Charles Hawkins, Le Gros Clark, Edward Cock, Samuel Lane, Alfred Baker, Sir Richard Owen, aged 87.

J. W. HULKE, *1895* (died on Feb. 19th; the Oration read by Thomas Bryant).—Hunter as a biologist. Movement of sensitive plants. Classification of animals.

CHRISTOPHER HEATH, *1897*, Surgeon to the University College Hospital.—Hunter's greatness as a surgeon. Reply to Jesse Foot. Work on aneurism and on venereal disease. Obituary notices of Hulke, Savory (refers to the early days of member's agitation for share in the government of the College). Durham, Erichsen, Humphrey, Spencer Wells.

SIR WM. MACCORMAC, *1899*, Surgeon to St. Thomas's Hospital (before the Prince of Wales).—General account of John Hunter. "The surgery of the Middle Ages was a trade. Ambroise Paré and Jean Louis Petit converted it into an art; John Hunter elevated it to the rank of a science." Animal heat; cranial surgery; aneurism. Venereal disease. Inflammation. Gunshot wounds. The Museum. Anæsthetics. Antiseptics. "Lister has finally crowned the edifice whose cornerstone John Hunter laid." Obituary notices: Oliver Pemberton, Bailey (Librarian), Rivington, Lund (Manchester), Lee.

N. C. MACNAMARA, *1901*.—Refers to the death of Queen Victoria. Obituary notice: *Sir James Paget*. Craniology. Refers to Sir Wm. Lawrence's lectures as being the first reference to the idea of the common origin of man and ape. Description of typical skulls.

H. G. HOWSE, *1903*, Surgeon to Guy's Hospital (MSS. only). Life and work of John Hunter. The greatness of his work in associating structure with function. Recent specimens. Hairy rhinoceros from Siberia. Casts and specimens showing evolution of horse. Obituary notices of Spencer Smith, Sir Wm. MacCormac.

JOHN TWEEDY, P.R.C.S., *1905*.—Obituary notices of Luther Holden, John Birkett, John Simon. "The greatest men are estimated by the influence they exert upon the thoughts and activities of those who follow them." Defence of animal experiments.

HENRY T. BUTLIN, *1907*, Surgeon to St. Bartholomew's Hospital.—Obituary notice of Christopher Heath. Description of Hunter's life and work. "(The great man) should see clearly truths which are still hidden to ordinary mortals."

HENRY MORRIS, *1909*, Surgeon to Middlesex Hospital (before T.R.H. the Prince and Princess of Wales, also Lord Rosebery and nine ladies and gentlemen of the Court).—Obituary notices of Sir Jos. Fayrer, Timothy Holmes, Wm. Allingham, Reginald Harrison, Sir Alfred Cooper, Prof. Charles Stewart (Curator). Hunter as a philosopher. The inductive method. A history of the intellectual movements in England, Scotland, and France. The conflict of the deductive and the inductive philosophies in Hunter's work.

EDMUND OWEN, *1911*, Surgeon to St. Mary's Hospital.—John Hunter and his Museum. Early life of Hunter. In July, 1768, at a Court of Examiners, John Hunter was examined and received his diploma (aged 40). Elected as a member of the Court of Assistants (Council) in 1789. He attended 14 meetings out of 26. Description of Hunter's inoculation with venereal disease and its effect on his arteries and death. Appreciation of Hunter, Pasteur, Lister.

SIR RICKMAN GODLEE, *1913*, Surgeon to University College Hospital.—Attributes to him the thought "What is life?" in the portrait. Mentions that Clift only received seven shillings a week for seven years. Reproductions of famous pictures: Hunter, Clift, Owen, Quekett, Flower, Stewart, and also of several of Hunter's house, museum, &c. Original 13,600* of Hunter's specimens increased to 64,766. Description of Museum. Imagining Hunter's return. Plea for a modern "institute of anatomy and pathology." Obituary notices of Dent, Butlin, Lister. Compares Hunter and Lister, taking nothing for granted, always experimenting, "body, blood, and motion."

SIR WM. WATSON-CHEYNE, P.R.C.S., *1915*, Surgeon to King's College Hospital.—Treatment of gunshot wounds. The problem of antiseptics.

SIR GEORGE MAKINS, *1917*, Surgeon to St. Thomas's Hospital.—Hunter as a military surgeon. Treatment of gunshot wounds. Limitation of antiseptics. Aneurism. Simultaneous ligature of artery and vein.

SIR ANTHONY BOWLBY, P.R.C.S., *1919*, Surgeon to St. Bartholomew's Hospital.—British military surgery in the time of Hunter and in the Great War. Conditions of military surgery in days of Hunter compared with those during the Great War.

SIR CHARTERS SYMONDS, *1921*, Surgeon to Guy's Hospital.—Life and work of Sir Astley Cooper. Remarks on medical education. Plea for more clinical and less preliminary work.

SIR JOHN BLAND-SUTTON, *1923*, Surgeon to the Middlesex Hospital.—*John Hunter—his affairs, habits, and opinions*. A description of Hunter's work, chiefly as a biologist, with many interesting references to recent discoveries—*e.g.*, the breeding of eels, the hearing of whales, and the early life of the kangaroo.

SIR D'ARCY POWER, *1925*.—Critical review of Hunter's illness with evidence of cerebral syphilis. Illustrations from Jesse Foot's life.

SIR BERKELEY MOYNIHAN, P.R.C.S., *1927*, Leeds (before H.R.H. Princess Mary).—Hunter's ideals and Lister's practice. The methods of the two great men and their results.

SIR HOLBURT WARING, *1928, Senior Surgeon to St. Bartholomew's* Hospital.—The progress of surgery from Hunter's day to ours.

Note.—The references to the Orations since 1913 are very brief, as these have been so recently published.

* The discrepancy between the figures given in 1834, 1846, and 1913, relating to the number of Hunter's specimens, is due to the fact that for years after Hunter's death further of his specimens came to light. Of these the largest group were the fossils, numbering 3709, found and described by Owen.

The controversial subjects referred to have been: the teaching of anatomy as the foundation of sound surgery; the emancipation of surgery from medicine; the problem of procuring bodies for dissection; the menace of quackery; and the agitation by Members of the College for a share in its government.

The chief matters of surgical advance have included: vaccination; scientific physiology and embryology; anæsthesia; bacteria and antiseptics; abdominal surgery and ovariotomy.

Notable stages in the advance of the College referred to have been: the granting of the Charter by George the Fourth; completion of the present building; foundation of the Fellowship; formation of the Conjoint Board; moving of John Hunter's remains to Westminster Abbey; and growth of the Museum from 13,600 specimens, bequeathed by Hunter to 64,766.

Six times the Oration has been delivered before members of the Royal Family, the first time by Cæsar Hawkins, before the Prince Consort in 1849, and the *last* by Sir Berkeley Moynihan in 1927, before the Princess Mary.

RECENT LOSSES.

When I undertook to deliver this Oration I had hoped to say that subsequent to 1913, its first centenary, all the orators were still with us, but now we have to deplore the death of Sir Anthony Bowlby, K.C.B., K.C.M.G., K.C.V.O., who gave the Oration in 1919 and was our President from 1920 to 1922. Intimately known and dearly loved by all the Bart.'s students who came under his kindly supervision, a sound surgeon and a wise teacher, Bowlby during the time of the Great War reached the zenith of his fame and influence. He served at the Front in France, during the entire conflict, and he was largely responsible for the organisation and equipment of the casualty clearing stations. No one in trouble at home or in the War ever applied to him for help without receiving it in the form of wise counsel and true comradeship.

Three other men notable in this College have also been recently claimed by death.

Thelwell Thomas, of Liverpool, was a Member of the Council from 1921 to 1927. His skill as a surgeon and his kindliness as a friend will always keep him in our memory, but in addition he has bequeathed the generous sum of £5000 to the College which the Council has determined to devote to the benefit of the library.

Thomas Horrocks Openshaw, for many years surgeon to the London Hospital, and chiefly known for his pioneer work in orthopædic surgery, was a member of the Council from 1916 to 1924. He was a safe surgeon and yet always abreast of the times, and his genial personality and splendid fortitude in the tragic death of his brilliant son greatly endeared him to us.

Mr. Victor G. Plarr was the librarian of this College from 1897 to 1929. His quiet and unobtrusive personality made him a stranger to many of our Fellows and Members, but he was always working for the good of the College. That by which he will be best remembered is the work he did in writing lives of the Fellows.

The publication of these lives under the editorship of Sir D'Arcy Power is now being undertaken, the expenses being defrayed by Thelwell Thomas's bequest.

We have also to deplore the loss of the last known descendant of the Hunter family in the person of Miss Helen Hunter Baillie, the great grand niece of John Hunter, who died in February, 1929, at the age of 86. She had been a regular attendant at these orations and had presented a valuable collection of letters and family documents to the library.

RECENT EVENTS.

Having given this brief tribute to the memory of men by whose labours surgery has been advanced, I would follow the example laid down by most of my predecessors in mentioning outstanding events in the history and progress of the College.

The agitation by some of the Members of the College for a direct share in its government, the idea of which was first referred to by Sir William Lawrence in 1846 in his heated denunciation of making the Royal College of Surgeons into a Royal College of General Practitioners and which was first actually mentioned by Christopher Heath in 1897, has continued year by year. It may be said now to have entered upon a new phase, insomuch that the annual meeting at which this topic is discussed, which at one time was the scene of angry strife, is now one of amity and goodwill. This amity has been further increased by Mr. Buxton Brown's generous endowment for the provision of an annual dinner, at which Fellows and Members meet for convivial intercourse.

It is not for me to say if and when the Council of this College will directly represent the 18,000 Members as well as the 2000 Fellows, but I may express a sincere wish that the change, which is in harmony with the modern democratic spirit may take place soon. The chief thing which is needed to bring it about quickly is convincing evidence that the change is desired by the great body of the Members.

The attainment of the Fellowship has been greatly facilitated for those in the overseas dominions by arranging for the primary examination to be held each year abroad. The first examination held last year in Canada was so successful that it will probably be repeated each year and a similar arrangement is now being made for Australia and New Zealand.

Mrs. Macloghlin has left £10,000 and the residue of her estate for the purpose of founding and endowing scholarships for medical students in memory of her husband, the late Mr. Edward Macloghlin, M.R.C.S., formerly in practice in Wigan. A sum of approximately £30,000 has been left by the late Sir George Mackenzie K.C.M.G., C.B., in memory of his friend Sir William Mackinnon, Bt., jointly to the two Colleges for the endowment of medical research.

The Honorary Medal, the award of which was instituted in 1802 for liberal acts or distinguished labours. . . conducive to the improvement of the healing art and which has only 12 times been given, was this year bestowed upon Sir George Makins, G.C.M.G., C.B., LL.D., F.R.C.S., in appreciation of his valuable services to the College, more especially in arranging and describing the series of drawings in the Army Medical War Collection.

Scholarships for research have been founded in this College. Lord Beaverbrook's gift of £1000 was quickly allocated for tissue culture work, and the need for more permanent endowment was evident. The Council has therefore set aside £500 a year for research work, and generous benefactions from Lord Melchett and Sir Louis Baron have placed at our disposal two more similar sums for a like object, so that there will now be expended on vital research a larger sum of money each year than was received by the College as its total income in the days when Hunter received his diploma.

One can hardly question that this movement of greater activity for research would have had Hunter's whole-hearted approval. He spent all his income on his museum and his experiments. The museum was bought by the nation and placed in our trusteeship.

We are proud to think that what originally was a unique collection of 13,000 specimens had increased to over 64,000 when Sir Rickman Godlee delivered his Oration in 1913, and now numbers 72,676, due largely to the addition of the military section acquired during the war, the Onodi and the Strangeways collections, illustrating respectively anatomy of the nose and diseases of the joints.

But Hunter's spirit of never tiring adventure in the search for knowledge, although belauded, has not hitherto been adequately followed.

We are too apt perhaps to be satisfied with what after all is only a collection of dead things and to forget that Hunter's absorbing thought was that of probing the secret and mystery of life. How he would have been thrilled if he could have used a modern microscope and yet more if under that instrument of precision he could have seen the living cells growing and dividing. It is, therefore, a happy thought that among the recent objects of research in this College is that of the culture of living tissues.

One of my predecessors, Sir Rickman Godlee, having spent many hours in the Council room of this College, gazing at the famous portrait of Hunter, became convinced that the look of wrapt attention and reverie on his face was an indication that he was absorbed in the contemplation of this great question "What is life?" The story of the portrait, well known to many here, is nevertheless worth repeating. Hunter had promised to sit for his portrait to Sir Joshua Reynolds, but he proved so restless a sitter that that great painter was in despair of ever getting a soul-revealing picture of Hunter's face. He had made an unsatisfactory beginning as his sitter fidgetted and grumbled, but then owing to some unknown cause, Hunter became absorbed in contemplation as we now see him. The painter without a moment's hesitation turned the canvas round and hastily but faithfully depicted the face at rest, painting it in the space between the legs of the original portrait. I believe that one of the reasons which has led experts to advise against this picture being restored is the fear that restoration might reveal a pair of inverted legs surrounding the leonine face.

We hope that the recent endowment of research and the building of the new laboratories may go a long way towards removing from us the reproach that whilst we have treasured and added to the *things* which Hunter left us we have lost sight of the *ideals* for which he was for ever striving.

Another auspicious event has taken place since the last Oration was given. The President of the Royal College of Surgeons has been elevated to a peerage. Only twice have surgeons been made lords. The first instance was that of Lister, who received his peerage when his days of active surgery were over but when he was the President of the Royal Society. In the second instance we are happy in the knowledge that not only is Lord Moynihan President of this College, but also that he is in the heyday of his surgical virility. Never has his brain been more active, his tongue more eloquent, his hand more firm, or his eye more keen. Because that eye is now upon me, I must desist from any further words of eulogy and I excuse those I have already uttered because it is of this College and the honour which he has brought to it that it is my duty to speak.

In Hunter's day surgery was only just emerging from the lowly position of serfdom to medicine. The very name of barber-surgeons indicated this status, half tradesman and half apothecary, and now two centuries later the Royal College of Surgeons is presided over by a peer.

HUNTER'S WORK ON BONES.

Thus far, Sir, my path has lain on conventional lines laid down by my honoured predecessors, and I felt that I could not venture further without seeking for advice and guidance. For these I have sought for inspiration to speak my best about the great Scotsman, John Hunter, from two other Scotsmen, both of whom like Hunter himself have come to this city to enlighten our darkness.

I asked Sir Arthur Keith and his answer was "Bones," and I asked Carlyle and he said "Heroes." In all diffidence, therefore, I will try to follow both their counsels, only asking you to aid my poor words with your imagination in thinking of Keith speaking to you about Bones or of Carlyle thrilling you with his rugged eloquence as he discoursed to you about "The Hero as a Surgeon."

A great part of Hunter's life was spent in handling bones. Anything big and strong and lasting had as much fascination for him as anything that was curious or inexplicable. His greedy longing for the skeleton of the Irish giant, satisfied at last by its nefarious purchase, is the best-known instance of this. Hundreds of skeletons of reptiles, fishes, birds, and mammals were prepared, articulated, and preserved by him and hundreds more were collected as fossils. Indeed, I suppose it would not be far from the truth to say that never before or since has any one man handled so many bones as Hunter.

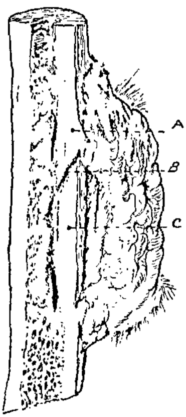
FIG. 1.

Shot in fowl's tibia. (AA') Shot. (BB') Points marking length of bone when shot were inserted.

But while his hands were busy with the bones his mind was busy with the questions of their formation and their growth. It is with his specimens dealing with these questions that we must occupy ourselves chiefly to-day. They fall into three categories. The first dealing with growth, the second with inflammation, and the third with transplantation.

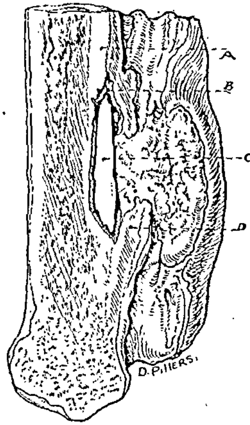
In Hunter's day bone was supposed to grow by a process of interstitial accretion. This was the doctrine of Du Hamel. True to his principle of "Don't think but try" Hunter determined to put this idea of bone-growth to the test. He buried two shot in the tibia of a young animal (both the pig and the fowl were used) two inches apart. (Fig. 1.) After a certain period when the animal had grown considerably it was killed and the shot were found to be the same distance from one another but much further from the two ends of the bone, thus proving that the growth in length of a bone was due to additions to its extremities.

FIG. 2.



Experimental necrosis. Early stage. (A) Living bone. (B) Granulation tissue. (C) Sequestrum.

FIG. 3.



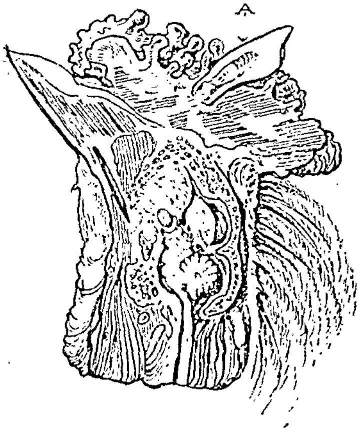
Experimental necrosis. Late stage. (A) Living bone. (B) Cavity containing sequestrum. (C) Sequestrum. (D) New bone growing over sequestrum.

Again, knowing of Belchier's discovery, that madder taken in the food is deposited in the bones, he fed young pigs upon food to which madder had been added. By giving and withholding the dye for varying periods and then killing the animals it was proved that madder-stained layers of bone were superimposed on unstained layers and that as new layers of bone were added to its surface the inner layer next to the marrow cavity was absorbed. He thus proved that the growth of a bone in thickness was due to the addition of new layers of bone to its outer surface and he recognised the occurrence of the physiological absorption of bone. He went further in this last observation, because he studied it in detail as it occurs in the shedding of a stag's antlers. He even anticipated some of the modern doctrines of internal secretions by noting the effect of castration in stunting the growths of the antlers. In one of Hunter's specimens, the head of a deer, in which the left antler is dwarfed, he tells us that from this animal the left testis had been removed.

In the second group of experiments Hunter demonstrated the process of inflammation, necrosis, sequestration, and the formation of an involucrum in a manner so perfect that his series of specimens stand to-day unique among our pathological collection. No better instance, I think, exists of how badly his tongue and his pen served his hand and his brain than is afforded by the laboured and involved description of the inflammation and necrosis of bones contained in Volume I., Chapter 18, of his collected works edited by Palmer as compared with the simple eloquence afforded by the specimens from which his learning was drawn. Most of these specimens were obtained by applying the actual cautery to one or other bones of an ass. (Figs. 2 and 3.) Possibly this was the same animal the tendo Achillis of which was divided and its union studied and on which other more elaborate experiments were performed. If this was the case then Hunter's ass certainly deserves a place in history even more honourable than that of Balaam.

In the third group of experiments Hunter showed how animal tissues could be removed from their natural situation and grafted elsewhere. In the most striking of these he cut off the spur of a cock and implanted it into the vascular comb. The transplanted spur not only lived in its new environment but grew prodigiously. An even more startling experiment was that of implanting a human tooth into a cock's comb and noting that having taken to its new bed it became vascularised, so that an injection into the vessels of the cock passed into the tissues of the transplanted tooth. (Fig. 4.) He transplanted the spur of a hen into the leg of a cock and obtained perfect healing with good growth of the transplanted bone. (Fig. 5.) This, I believe, is the first instance of successful bone-grafting of which we have any record.

FIG. 4.



Tooth transplanted into cock's comb. (A) Tooth.

In Hunter's day it was not possible to carry out any but the most simple experiments with bones, because any deliberate exposure and cutting of bone was followed by septic inflammation. Since the advent of aseptic surgery, however, the bones have proved amenable both to experimental work as well as to surgical operations.

MACEWEN AND LATER WORKERS.

There have been added to the Museum two notable series of experimental specimens, the one by Sir William MacEwen and the other by the Jacksonian Essayist of 1913.

The one series is of great scientific and historical interest, because it really settled what may be called the battle of the periosteum once and for all.

Until MacEwen's work, the periosteum was regarded as the veritable matrix of the bone, chiefly because of the work of Ollier of Lyons. But MacEwen showed that bone could grow and live without periosteum and that the so-called periosteal new bone was merely bone which had grown into the periosteum from its basal attachment and that the periosteum is merely an inert limiting membrane. These ideas were at first scouted by American and continental workers, but that they have now been converted is proved by the words of Leriche, Ollier's most brilliant pupil. "An area of ready ossification, the periosteum is not a specific organ of osteogenesis," and "the functional characteristic of periosteum appears to reside in the imitation of ossification."

Quite recently Cowan, an American worker, has shown that not only does the periosteum not produce new bone, but that it is one of the chief agents in preventing the union of fractures, by its capacity of forming dense fibrous tissue, which is apt to grow between the fragments and so hinder the union of the callus which these produce.

But the ultimate mystic problem of how bone is laid down and again taken up is not only still far from solution but seems now to us much more complex than it was in Hunter's day. We know a little of some of the distant forces which determine how much bone shall be laid down or to what size or to what density it shall grow.

We know that the ductless glands, the pituitary, the thyroid, the parathyroid, the ovaries have some influence on the growth of the skeleton, that food elements which can neither be isolated nor analysed, the vitamins, may determine its density, and most mysterious of all, that not only can sunlight cause bone to grow but that this sun power can be first given to the food and by this transferred to the bones.

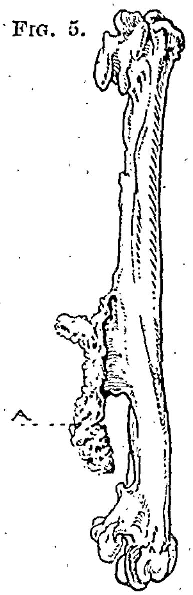
In fact the whole bewildering chapter in physiology called calcium metabolism appears to concern itself with all aspects of life and growth. But even the simple facts of the relationship between bone salts and bone cells are still matters of doubt and dispute. That animal tissues can be grafted was proved by Hunter, but the exact changes which take place in this process are most difficult to understand or explain.

Hunter took it for granted when he transplanted a human tooth into a cock's comb and it remained in organic connexion, allowing injection from the bird's vessels to permeate its tissues, that the tooth had become a living part of the cock's tissues. The modern view, however, would be that the vascularisation was only that of granulation tissue, by which the foreign tooth would have been eaten away and destroyed.

BONE-PLATING AND BONE-GRAFTING.

As I have said before, no practical advantages could have followed in Hunter's time from his grafting experiments. But in the modern era of aseptic surgery bone-grafting has become an everyday method of repairing fractures and of making good defects in the bones. For a time, it is true, the possibility of suture and fixation of bones by metallic substances, wire, plates, screws, and the like absorbed the attention of surgeons. But both clinical experience and experimental work soon showed the drawbacks and limitations of the use of metal substances and proved the great possibilities of grafting with bone tissue.

FIG. 5.



Bony spur grafted into leg bone of a fowl. (A) Spur.

The Jacksonian specimens illustrate many of these points, of which the following may be mentioned as the most important.

Any metal substance, whether wire or screw, exerting firm pressure upon living bone, causes either necrosis, or else absorption of the bone, and therefore is to be regarded as essentially a hindrance to bone growth or repair. This bone destruction, whether by necrosis or absorption, is a vital and not a septic process, but it leads to conditions very favourable to the latter. When, however, metallic fixation is efficient and bone union occurs there is produced in the end a reactive inflammation by which the foreign body becomes encased in a layer of dense new bone. Thus the method used clinically may and often does lead to painful osteitis which finally requires the removal of the offending metal.

In regard to bone-grafting the specimens under consideration give by no means a complete picture of the process. But they do illustrate two points of cardinal importance. The survival and functional union of the graft to the host bone depends essentially upon perfect contact and adequate fixation between the graft and the host. No living graft, however carefully cut even from the same animal, will survive or function if it is laid loosely into the tissues of the host. In other words, the graft manifests no innate vitality of its own. Further, if two small grafts taken, one of living autogenous bone, the other of dead, boiled bone, be fixed firmly in the shape of pegs into holes bored in the living host bone, then at the end of six weeks both will have grown in place and neither naked-eye nor microscopical examination can detect any difference. Dense bone when transplanted always dies, in the sense that its cell spaces and vascular channels become empty. It is then invaded by new vessels and inhabited by new bone cells provided by the tissues of the host. From this it follows that in many cases it is just as good to use dead bone in the first place and to trust to the activity of the host's tissues to vascularise and vivify it. Of this I shall show you a convincing proof presently. But it would be going too far to assert that the living autogenous graft has no advantage over the dead one. Certainly when a gap in a bone has to be bridged the living graft becomes a vital and growing part of the skeleton much more surely and more quickly than does a dead graft. Therefore in such cases as making good the gap left by the destruction of the whole diaphysis by osteomyelitis or the fixation of a tuberculous spine by the insertion of a tibial graft—a suggestion which we owe to the genius of an American colleague Dr. Albee—it is better to use the living bone taken from the patient himself. Whether this superiority of the live graft is due to the survival of superficial cells or to its more ready permeability by the host blood-vessels we do not know—but it is certainly not due to the survival of the graft as a living entity.

In the beautiful specimen lately presented to the Museum of a double bone-graft of the spine, obtained three months after the grafting operation, the grafts are seen to be in close vital union with the vertebræ. (Fig. 6.) But it is evident that the great vascularity of the grafts represents a new process of permeation and invasion by new blood-vessels, as the tibial crests from which they were taken contain no such blood channels.

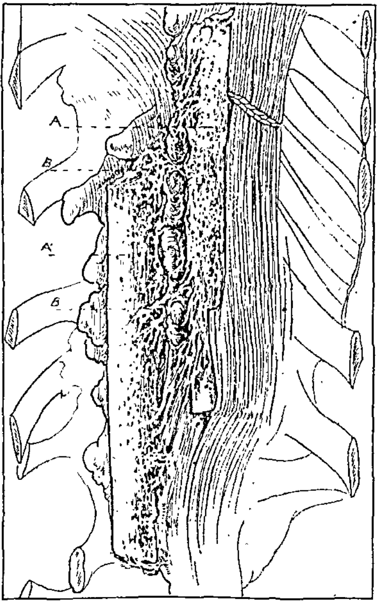
Probably I have raised in the minds of many of my hearers a feeling of scepticism about the possibilities of dead bones being capable of functioning as real vital grafts—vital, that is to say, in the sense that they become an integral part of the living skeleton.

Therefore I will venture to give you three illustrations, which I am happy to say are not dead specimens in bottles, but living healthy people.

The first is from a lady of 39, who had an ununited fracture of the neck of the femur of two years' duration. The bone was mended by exposing the hip-joint and nailing the head of the bone to the neck after the former had been dislocated. For this purpose a nail made of dead bone cut from a stag's antler and 3 in. long and ⅜ in. thick was used. She made a rapid and complete recovery and to-day, three years after the operation, it is impossible to detect from her active movements which of the hips has been injured. The X rays show very well how the bone nail first merely held the broken neck of the femur together (Fig. 7 A, B, C, D), then slowly but surely became incorporated into the living skeleton.

The second instance is in a man of 25, who at the time of the operation was 18. He had developed fibrocystic disease in the upper part of the left femur, which had become reduced to a mere shell of bone, causing a definite aching pain, premonitory of a spontaneous fracture. The exact nature of the condition was revealed by a preliminary operation in which a mass of firm fibrous tissue was revealed occupying the whole cavity, shown by the X rays. An exact model of this cavity was prepared from a tooth of a walrus, which by its curve and size seemed just made for the purpose. The whole cavity in the bone was exposed by cutting a trap door from the back of the femur, the fibrous mass was removed in one piece, and the ivory graft inserted. (Fig. 8 A, B.) There it remains to this day, surrounded but not replaced by the human bone, the dense ivory having proved resistant to penetration by new blood-vessels. The patient, a quarry-man, has been in good health and active work ever since. It is to me a happy thought that whilst Hunter was able to graft a tooth into a cock's comb 150 years ago, we have succeeded in implanting a walrus tooth into a man's leg in such a way as to form an integral part of his skeleton.

FIG. 6.



Autogenous tibial graft into human spine. (AA') Grafts. (B) New bone growing into grafts.

The third instance is perhaps the most instructive of all, because the dead graft was made to bridge a gap and has been associated with very active growth of a long bone. The boy as he then was, 10 years ago, between the ages of 7 and 10, had broken the right humerus four times, *usually as the result of trivial* violence. The X rays showed a cyst in the middle of the shaft of the bone. (Fig. 9 A.) The whole thickness of the affected portion of the bone was cut out for a length of three inches by a subperiosteal resection and you see the specimen thus obtained. (Fig. 9 B.) The gap was made good by thrusting a long piece of beef bone into each fragment and then bolting together the projecting ends of the grafts. Each graft had had many small drill holes made into it, in order to facilitate its penetration by living tissues. He made a smooth recovery without the use of any splint and was able to return to the dangerous environment of public school life six weeks later. The X ray pictures will show you how the beef bone has remained in place for ten years, becoming gradually merged, especially at the ends in the structure of the human bone. (Fig. 9 C, D.) That this bone has suffered no diminution of growth from its invasion by an ox bone is evident from the pictures but that you may be finally convinced of this I have brought the gentleman himself to show you, and you will admit that the addition of a piece of beef bone to his anatomy has not interfered with his growth. (He is now 6 ft. 2 in. and an undergraduate at the University.)

I have selected the study which Hunter made of bones and some of the things which have arisen from it as an example of his work, chiefly because it has not been touched upon by any of my predecessors and also because it is most familiar to myself, and this leads me to my first observation about Hunter as a great man. Think of it!

Seventy-five orations about one man and his work and still there is left a great subject almost untouched.

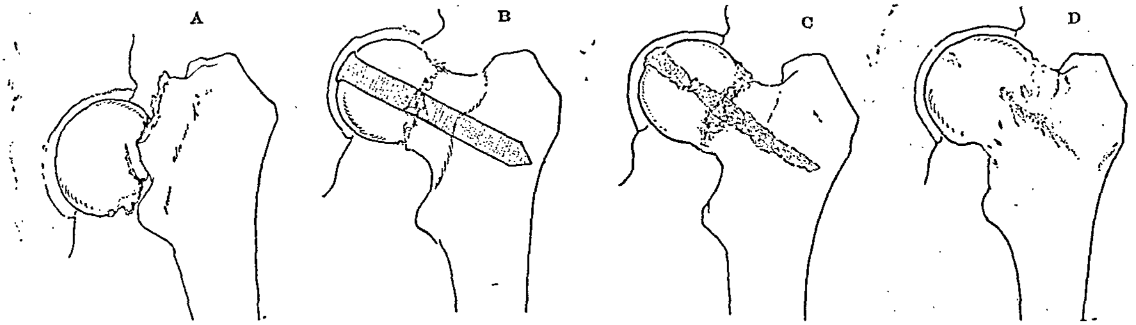
HUNTER AS A WORKER.

The first, but I will not say the greatest claim, which Hunter makes to be regarded as a veritable giant among men is his capacity and enthusiasm for work. He came as a young man from Scotland and began his life in London; making anatomical preparations in the school of his elder brother, William, he then taught anatomy and got himself qualified after working at Chelsea, St. Bartholomew's, and St. George's Hospitals. He was already deeply engaged in scientific research work chiefly in dissecting all the animals he could get. His health threatening to break down, he applied for and obtained a military surgeon's post and served for three years in Belle Isle and on the Peninsula.

On his return to London, his practice having vanished, he began strenuous work in dissecting, describing, and collecting specimens, which was the beginning of the present Museum. He became a surgeon to St. George's Hospital, he lectured on anatomy and surgery. He acquired a great and prosperous practice, and with its proceeds bought a country place at Earls Court in which he collected a veritable menagerie of wild animals and continued with his experiments. He became the Deputy Surgeon-General of the Army Medical Service. He had been for a long time a Fellow of the Royal Society and was already engaged in writing and contributing scientific papers for that learned body. Before he reached the zenith of his fame he had begun to suffer from attacks of angina pectoris, all the symptoms of which he relates with vivid exactitude.

His whole day being taken up with his practice and his teaching and his body racked with an ever-progressive disease, his last thought was of seeking rest or repose. On the contrary, his passion for work kept him up until midnight writing and awakened him again at four in the morning when he settled down to his dissecting. If a stranger wrote to him, wishing to see his work and profering an introduction from another distinguished surgeon or scientist, Hunter would name 5 A.M. as a suitable hour for an appointment! This all sounds incredible but its truth is vouched for by many witnesses, including Hunter's arch-enemy, the notorious Jesse Foot.

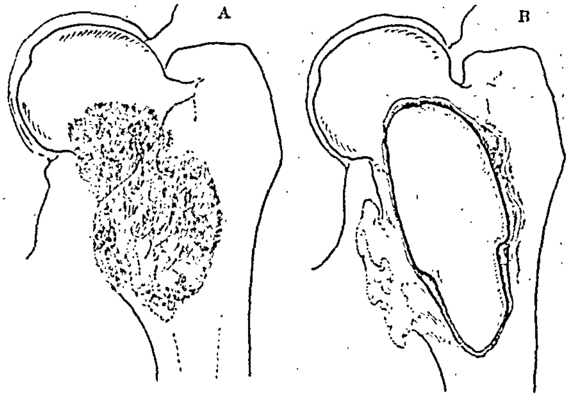
FIG. 7.



Dead graft in human femur. (A) Before operation. (B) Two months after operation. (C) One year after. (D) Two years after.

But in addition to witnesses from the past we have the convincing evidence afforded by 13,600 specimens in the Museum. It is not easy to grasp in a moment the significance of these figures. Hunter began his work at the age of 20 and died at 65. Allowing then full 45 years and 300 working days in each we have the total of 13,500 days with 13,600 specimens collected, or an average of one specimen for every day of his life. Many of these necessitated experiment or elaborate dissection, and he also left many folios of drawings, notes, and descriptions, besides those destroyed by Home and the 55 papers or treatises written by Hunter or prepared from his notes after his death.

FIG. 8.



Ivory graft in human femur. (A) Femur before operation showing fibrocystic disease. (B) Disease excised and cavity filled by ivory tooth seven years later.

A few people there may be, but very few who in intellectual pursuits really do work hard, but how many of these continue their self-imposed slavery right up to the end of their lives, even when fame and fortune have smiled upon them?

Hunter knew full well that he was suffering from a mortal disease, for he told a friend that his life was at the mercy of any rascal who chose to anger him and yet he went on at full pressure to the day of his death, when his own prediction came true and some colleague giving him the lie in the board room of St. George's Hospital he felt that the fatal blow had been struck and expired in the arms of Dr. Robertson.

HUNTER AS A SEEKER.

And this brings me to the next point which unhesitatingly may be said to be his chief claim to greatness. And this is the driving force which lay behind his work. Hunter was desperately in earnest. He was inspired by a vision of the mystery of life, which called him on and ever onwards, trying, experimenting, asking and seeking to know something of the truth of life and nature. "No man adequate to do anything, but is first of all in right earnest about it; what I call a sincere man. I should say sincerity, a deep great, genuine sincerity is the first characteristic of all men in any way heroic." That sentence of Carlyle's I take as literally applicable to our hero.

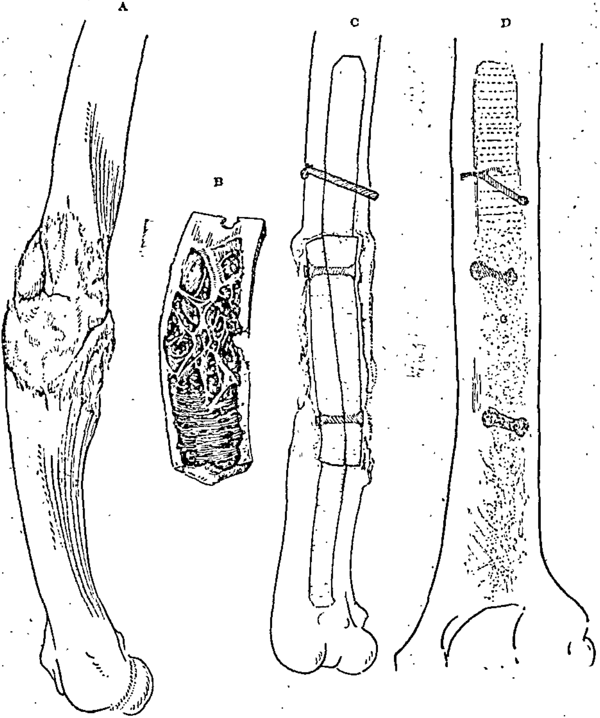
Nothing serves better to illustrate Hunter's desperate enthusiasm for research than his own deliberate inoculation of himself with disease. Unhappily this experiment was only too successful, though he himself failed to understand what has been so amply demonstrated by others that this disease, when it had apparently disappeared, laid relentless hold upon his blood-vessels and led to angina and to his tragic death.

It has been many times claimed that Hunter's secret lay in his having adopted the Baconian or inductive philosophy. But others have justly remarked that he often allowed himself to lapse back into the deductive method and that whenever he did this he wandered from the path of truth. It is highly improbable that he ever consciously adopted any philosophic system. He just went straight to Nature and demanding to know the answer to her riddles he thought nothing of giving his fortune and his life as a price for his knowledge.

In biological science Hunter was the greatest seeker the world has ever known, though by no means the greatest finder. It was his desperate earnestness in seeking and not merely the products of his research which then and now rivets men's attention. It was an arresting spectacle to see a Scotchman spending £70,000 in collecting specimens which had no intrinsic value. It was his supernatural faith that there was in Nature something worth seeking, which made other men follow his lead. The mere sight of a man earnestly gazing at some object in the street is enough to draw a crowd who will endeavour to find out what all are looking for. The pioneer who refuses to be satisfied with the bare tillage of the surface soil, worn poor by many generations of cultivators and convinced that a rich vein of gold is to be had for the digging, spends all his energies, his fortune and his life, in delving into the earth for buried treasure—who brings up many strange things, which at first only a few know to be auriferous ore—this is the man whose faith and enthusiasm compel others to follow. The pioneer does not himself, may be, find the largest nugget, or the purest gold, but he shows where gold may be found and how to find it.

Such a pioneer was Hunter and to Lister coming after him was accorded the good fortune to bring to light the most precious treasure that the surgeon-digger has ever given to his fellow men. It was John Hunter's faith and vision which raised surgery from the level of a craft and art to that of a science, and which has proved an inspiration to his followers. "For consider," as Carlyle says, "what mere time will do in such cases; how if a man was great when living, he becomes tenfold greater when dead."

FIG. 9.



Dead graft in human humerus. (A) Humerus before operation showing fibrocystic disease. (B) Portion of humerus excised. (C) Humerus reconstructed with beef bone, three months after operation. (D) Same case ten years after operation.

HIS HUMAN FRAILTIES.

The wonderful influence which Hunter exerted upon contemporary thought is made much more remarkable when we consider his many shortcomings and frailties.

He was gifted neither with learning nor eloquence. Of his writings I am almost tempted to quote what Carlyle says of Mahomet's Koran: "I must say it is as toilsome reading as I ever undertook. A wearisome, confused jumble, crude, incondite; endless iteration, long-windedness, entanglement." I sometimes wonder whether his brother-in-law, who afterwards became Sir Everard Home, the first President of the Royal College of Surgeons, deserves all the obliquy which has been heaped upon him for taking a cartload of Hunter's unpublished writings away with him and quietly destroying them, after he had extracted so much learning from them as by papers contributed by himself to the Royal Society, earned him a Fellowship in that body.

Although Hunter lectured for many years he found it a painful task and often took laudanum beforehand to quiet his discomforture. He had none of the classic learning considered essential for a scholar in his day, and even when he had a chance of acquiring it at Oxford he impatiently threw it aside, saying that he would rather learn from living Nature than from dead languages.

Even in those uncouth days Hunter was a rough customer. He was always quarrelling—whether with fellow officers in his military service or with his own brother, or other workers at home. He bursts into his wife's drawing-room and addresses her visitors: "I knew nothing of this kick-up, I ought to have been informed of it beforehand, but as I am now returned home to study I hope the present company will retire." It seemed that he must quarrel even to the end, even though it cost him his life.

If it should seem strange to mention these human frailties when speaking of one who was truly a hero, if ever there was one, I do it deliberately in order to emphasise that Hunter owed his influence to the greatness of his work, the almost blinding sincerity of his vision, and to his unquenchable enthusiasm, rather than to any charm of manner, or polish of language. I must quote Carlyle again when he says: "On the whole we make too much of faults; the details of the business hide the centre of it. Faults? The greatest of faults, I should say, is to be conscious of none."

His Heritage and Inspiration.

To the whole surgical world who have come after him Hunter's most priceless bequests have been his inspiration and his heritage. The heritage is here as the most wonderful museum of its kind in the world, the inspiration is impossible to limit or define.

We know that Hunter's experimental methods laid the foundations of modern physiology and pathology. He taught us to seek out the relations between structure and function in the normal tissues and between disorder and disease in the morbid. In his collection of animals and of fossils and his observations on development with its parallelism between the growth of the individual and the elaboration of the race, he came very near to the Darwinian theory of evolution. His methods, closely followed by Lister, were the basis of the discovery of the antiseptic treatment of wounds. "Worship of a hero is transcendent admiration of a great man." The great turbulent heroic soul of Hunter has never lacked this worship, or else these 76 Orations have been poor sham mockeries.

Even if we admit that orations are but empty words, there exists a far more vital evidence that the torch of inspired enthusiasm has been faithfully handed down from his day until now.

First, there was that dear old man Clift, who like a watch dog guarded his master's treasures after his death, when it seemed that nobody wanted them. For seven years he lived on 7*s*. a week, whilst he kept his trust and then later became the first formal custodian of the Museum. The watch dog growled and showed his teeth, but alas could do no more when his master's precious papers, many of which Clift had himself helped to write, were carted away and secretly destroyed by Home.

Clift's daughter married Richard Owen, who succeeded him in the guardianship of the Hunter Museum and became the greatest palæontologist and comparative anatomist of his day. He was later transferred to the Natural History Museum at South Kensington. Owen was followed by Paget, a most notable torchbearer, whose ceaseless labours added so much to surgical pathology and whose silver-tongued eloquence is remembered by many now living.

Then came the greatest of Hunter's followers, Lister, whose name is held in honour all the world over as the one whose work has saved more lives and suffering than have been sacrificed by war. Lister, it is true, never held high office in this College, though he was a Member of Council for eight years. His gentle soul did not love fighting with his detractors, and he preferred to pursue his quiet research in the laboratory and at the bedside.

And lastly we are fortunate in having to-day, in the person of our beloved Curator, Sir Arthur Keith, one on whom the mantle of John Hunter seems perfectly to rest, the depth of whose learning and the eloquence of whose tongue fits him so well to be the guardian of Hunter's heritage and the exponent of Hunter's inspiration.

Hunter may truly be said to have raised the idea of the scientific pursuit of truth to the level of that compelling influence in men's lives which is called religion. For he had a vivid faith in his quest, an unquenchable enthusiasm for his ideal; he left an inspiration for all who come after him and a real hero for us to worship.

PSITTACOSIS.

A FURTHER ACCOUNT OF CASES OF HUMAN INFECTION.*

ASSISTANT PHYSICIAN TO THE GENERAL HOSPITAL BIRMINGHAM; PHYSICIAN TO THE CHILDREN'S HOSPITAL, BIRMINGHAM.

With Bacteriological Reports by

W. T. Hillier, M.R.C.S. Eng.,

CLINICAL PATHOLOGIST TO THE GENERAL HOSPITAL.

In a recent communication[1] I published a brief review of psittacosis and described four cases of human infection that had come to my notice. My reason for returning so soon to the subject is that I have since met with no less than 17 further cases, which are recorded fully below as Cases 5–21. Five of them I myself did not see, but the clinical details leave no doubt of the diagnosis. Of the remaining 12, two (Cases 6 and 7) were not sufficiently clear to warrant a final opinion, but I regard them as probable instances of mild infection.

The fact that so many cases, in so short a time, have come to the notice of one physician seems to justify the tentative opinion that I expressed previously, that sickness of this type is by no means rare. It is true that in Cases 5, 6, and 7 I was consulted as a result of the publicity given to my first paper by a daily newspaper, but most of the others occurred in the ordinary course of practice, and I saw them as unsolved problems of obscure pyrexia. In several instances a fairly confident diagnosis was made on purely clinical grounds, a history of contact with sick birds being elicited only later.

From various lay and medical sources I have received accounts of obscure illnesses which give reasonable grounds for the belief that they were in fact due to psittacosis, but I have thought it wise not to publish these.

A Group of Three Cases.

For information and help in preparing the record of Cases 5, 6, and 7 I am indebted to Dr. W. Geoffrey Shaw, of Weaverham, Cheshire, who had charge of them, and to Dr. W. H. Grace, pathologist to the Royal Infirmary, Chester, who saw them in consultation.

On June 27th, 1929, Mrs. A bought a young parrot from a dealer in London. The day after its arrival in her home the bird appeared to have a "cold"; a little later the feathers became ruffled and were shed freely and there was a frothy discharge from the nose. Diarrhœa set in on July 20th and on the 22nd the parrot died. The bird had been much petted by Mr. A, who had trained it to walk up his arm and take a lump of sugar from between his lips, and his little son had often played with it. Mrs. A cared for it during the later stages of its illness. On the day that the parrot died Mr. A (CASE 5), who had appeared unwell for two days previously, collapsed at his work and on returning home was found to have a temperature of 103° F. As Dr. Shaw could find nothing to account for the fever, he invited Dr. Grace to see the patient the following day, and the latter has kindly sent me the following report.

---

* The greater part of this communication was read to a meeting of the Royal Society of Medicine, Section of Medicine, on Jan. 28th, 1930. An account of four additional cases, and a discussion of the ætiology in the light of the investigations published since then, is now incorporated.

"When I first saw him he had a distinctly high temperature and felt ill. Clinically, to me, he did not quite fit in with a case of typhoid or paratyphoid; the onset was rather sudden—although I tried to persuade myself that he had been walking about for some time with a pyrexia and had refused to give in—and he seemed to be more suddenly ill that one usually finds in one of the typhoid group infections. When I saw him he was almost on the point of a rigor, his conjunctivæ were very injected and he was more brightly spoken than one usually sees in typhoid or paratyphoid infection. I could not see any spots, nor could I feel his spleen or find anything abnormal in the chest. I tested some of his serum with the Medical Research standard agglutinable emulsions of typhoid and paratyphoid A and B. To my surprise he gave quite a quick and complete agglutination of the *B. typhosus* up to 1 : 300 and a slight agglutination of the *B. paratyphosus* A and B to 1 : 10. With these results I was prepared to throw overboard my clinical impressions and, for the moment, call the case one of pure typhoid and advise its treatment accordingly. I have since examined fæces, urine, blood, the parrot's perch, and scrapings from the bottom of the parrot's cage, but in no case have I found a non-lactose fermenter."

Mrs. A, from the very beginning of her husband's illness, had insisted that he had been infected from the parrot and searched any literature that she could find bearing on diseases of birds that might be transmitted to men; she had no success, however, until she came across a paragraph in a daily newspaper referring to my first paper in THE LANCET, which she immediately obtained. In these circumstances I saw Mr. A in consultation with Dr. Shaw on July 28th. For the previous six days his temperature had been constantly high, between 103° and 104° F., but his pulse-rate had remained slow; it never reached 100 per minute and was usually between 80 and 90. He was flushed and sweating profusely and complained of intense headache: he was mentally clear, but at times he had been mildly delirious. An irritable cough had developed two days previously, and as I entered his room he expectorated some rusty sputum, but this never recurred.

On examination I found, at the right base in the axillary line, some fine crepitant râles and a patch of rather doubtful faint tubular breath sounds. Dr. Shaw and I agreed that at that stage he looked rather like a case of pneumonia. There was no serious abdominal distension; the spleen was not palpable and there were no typhoid spots, merely a few sudamina. The bowels were costive. A blood culture I made at the time proved sterile (as did Dr. Grace's) and I recovered nothing of significance from a post-nasal swab. The piece of rusty sputum that I took away with me yielded a Gram-negative, non-lactose fermenting bacillus, but I was never able to get it in pure culture and eventually it died out.

Later Dr. Shaw sent me the following report on the progress of this case: "As far as the clinical aspect was concerned, he appeared to be a typical typhoid. The temperature curve reached its maximum at the beginning of the second week, then remained at a steady 100°–101°, and in the third week came down by lysis. During the whole febrile period he complained of intense headache and had troublesome cough, with scanty muco-purulent sputum. The tongue was thickly furred and the bowels were obstinately constipated throughout. The small spot in the right lung, where you suspected a commencing broncho-pneumonia, did not extend and there were no further pneumonic signs. The pulse-rate remained slow (about 80–85) and of good tension throughout the illness. His convalescence was uneventful."

Two or three days before Mr. A became seriously ill, his son (CASE 6), aged 7 years, fell sick with an acute febrile attack (on one occasion the mother found a temperature of 103°). After four or five days the temperature became normal, but it continued to go up to 99° each evening for a fortnight. During that fortnight he always declared that he felt perfectly well; he certainly had no symptoms of any kind except constipation, but looked rather pale and "washed-out." I examined this boy with Dr. Shaw on July 28th and agreed with him that there were no abnormal physical signs. It is probable that this child was infected from the bird, with which he had been in close contact, for he became ill at about the same time as his father and it is well known that in children infections of the typhoid group run a much milder course than they do in the adult.

Mrs. A (CASE 7) had a remarkable experience. On July 25th, when her husband had been in bed for three days, she complained of backache and of feeling ill. On the following day, in view of Mr. A's positive Widal reaction, she was given a protective dose of T.A.B. vaccine (500 millions of *B. typhosus* and 250 millions each of *B. paratyphosus* A and B). One and a half hours after the inoculation she had a rigor and became collapsed; her temperature was moderately raised during the next four days and she had a slight cough with mucoid expectoration. Her subsequent progress was uneventful. At the same time that she was inoculated her maid received a similar dose, with the usual consequence of a slight feeling of illness and a trivial temperature 24 hours later.

The very severe reaction shown by Mrs. A to the vaccine suggests that she was sensitised to an organism of the typhoid group, and it may be that at the time of inoculation she was incubating an infection similar to that of her husband. If this was so, the vaccine cut short the attack in a remarkable way.

Further Clinical Histories and Bacteriological Findings.

CASE 8.—On August 12th, 1929, Mrs. B, a lady of middle age and the wife of a doctor, took charge of a young parrot which was confided to her care by some friends because it had become sick and she was known to be interested in birds. During the next fortnight the parrot became extremely ill, with vomiting and profuse diarrhœa of a very offensive kind; nevertheless Mrs. B tended it assiduously and managed to restore it to its owners alive on August 26th, but it died three days later. On Sept. 1st, five days after parting with the parrot, she developed a headache and felt shivery; her temperature was found to be 100° and she went to bed. During the next five days the fever steadily increased to 103·5 and the headache became more severe; it was mainly occipital in distribution but sometimes diffuse. There was some diarrhœa during the first three days and she frequently vomited, particularly after taking medicine.

I saw her first on Sept. 6th, in consultation with Dr. T. M. Tibbetts of Stourbridge. The temperature was nearly 104° but the pulse was slow, just over 90 per minute; she complained of intense headache but was mentally quite clear and bright. Some sharp crackling râles were heard in the third left intercostal space, but apart from this, a dirty tongue, and moderate abdominal distension, physical examination was negative. I was at once struck by the resemblance of this case to the one I had seen a year previously and on inquiry elicited the history of contact with the sick parrot, which warranted a fairly confident diagnosis of psittacosis.

The next day the patient was admitted to the General Hospital; she had slight epistaxis just before she left her home. During the next 13 days the temperature slowly fell by lysis from 104° to normal. The pulse-rate hardly ever reached 100 and respiration was never seriously hurried. Despite the gradual fall in the temperature the general condition appeared to become worse, and she was very gravely ill during the whole of the febrile period and for a week afterwards. The signs in the left lung gradually extended. On Sept. 8th rather coarse crepitant râles were heard over the whole of the left upper lobe in front; on Sept. 9th there was definite dullness above the left breast, reaching to the axilla, and crepitations were heard at the back. Tubular breath sounds were found on Sept. 10th in the left axilla, and coarse crepitant râles were present throughout the whole of the left lung. By Sept. 13th the breath sounds in the left lung became faint and were hardly audible on the 16th; during the four following days the left lung was almost completely silent and the percussion note over it was dull. A lung puncture on Sept. 18th proved the absence of fluid. Subsequently a few crepitations appeared in the lung and the physical signs eventually cleared up by Sept. 30th, when the temperature had been normal for ten days. Cough was never severe, but she had a distressing hiccough for some days. There was practically no expectoration. The spleen was never palpable and there were no true typhoid spots (though one suspicious spot was noticed on the flank in the early stages). Occasionally she had diarrhœa and passed loose greenish stools, but this may have been due in part to the measures adopted to relieve abdominal distension, which was of extraordinary severity. She often became acutely distended in the course of an hour or so; injections of pituitrin and eserine with turpentine enemata generally produced immediate relief with the passage of vast quantities of flatus and a visible diminution in the size of the abdomen, but within an hour she was frequently found to be as tense as before. On one occasion the passage of a tube led to the escape of so great a quantity of flatus that she had a serious collapse, similar to that sometimes seen during operations for the relief of acute intestinal obstruction. Subsequently, to avoid this, the flatus tube was clamped and the gas allowed to escape slowly. On Sept. 11th she became very drowsy and on the 13th completely stuporose; for six days she never spoke and seemed entirely oblivious to her surroundings. Her face had a mask-like immobility, with a curious retraction of the upper eyelids, so that a wide rim of sclerotic could be seen above the pupils; blinking occurred very seldom. At times slight weakness of the sixth or seventh cranial nerves on the right side was suspected, and very severe bilateral ankle-clonus was present for several days. The tendon reflexes were exaggerated, and on one occasion an extensor plantar response was found on the right side. The fundi were normal, but for one day the right pupil was much larger than the left, though reactions to light were brisk in both. Incontinence was frequent. Her general appearance was suggestive of parkinsonism, and Dr. Stanley Barnes, who saw her with me, thought there was no doubt of it. As she slowly recovered from the stuporose condition she was completely disorientated in place and time, and later on she told me that she had no recollection at all of this period of her illness. The incontinence persisted for some days after the disappearance of her other nervous symptoms, and three weeks after the temperature fell to normal her memory was found to be still impaired. Eventually she made a complete recovery.

Her husband received a protective injection of T.A.B. vaccine at my suggestion on Sept. 7th, and we gave her three small injections (about 7·5 c.cm. each) of his serum on the 15th, 19th, and 20th, but they appeared to have no appreciable effect on the course of her temperature. In view of the result of similar injections in Case 9, it is probable that so soon after his inoculation the husband had not accumulated sufficient antibodies to be of value.

Bacteriological Report.—Four specimens of fæces were examined. Those of Sept. 9th, 11th, and 18th yielded no non-lactose fermenters. That of the 12th yielded an organism giving gas only in glucose and lactose broth, acid and clot in milk, acid and gas in dulcite, maltose, and mannite, and no reaction in saccharose and inulin. The presence of acid and clot in milk culture renders it possible that this organism, which in some respects is rather like *B. aertrycke*, was in reality a lactose fermenter and, if that be so, all the four specimens of fæces gave negative results for *B. psittacosis.* The blood culture, taken on admission, was sterile, and a post-nasal swab yielded no non-lactose fermenters.

The urine (Sept. 7th) yielded an organism identified by its sugar reactions in 48 hours as *B. fæcalis alkaligenes.* Cultures from a lung puncture (Sept. 17th) produced an organism which, by the sugar tests, resembled *B. fæcalis alkaligenes*, but which was non-motile and so short that it was impossible to be certain whether it was truly a bacillus or a coccus.

B. psittacosis, then, was not found in fæces, urine, post-nasal swab, fluid from lung puncture, or blood. *B. fæcalis alkaligenes* was obtained from the urine (and possibly from the lung).

Agglutination tests against *B. typhosus*, *B. paratyphosus* A and B, salmonella (Mutton and Newport) on Sept. 8th and 10th (in the second week of illness) were completely negative. Serum taken on Sept. 19th, however, agglutinated 24-hour broth cultures of *B. psittacosis* (Perry) National Collection of Type Cultures 1 : 500 and organism *B. fæcalis alkaligenes* from the urine, broth culture 1 : 40, but there was no agglutination with *B. typhosus* or *B. paratyphosus* A or B. On Sept. 26th, a week later, another specimen of serum failed to agglutinate broth cultures of *B. psittacosis*, *B. fæcalis alkaligenes* or salmonella (Mutton), but with a suspension from an agar culture in normal saline it agglutinated *B. fæcalis alkaligenes* at 1 : 80. Saturation with either *B. psittacosis*, salmonella (Mutton), or *B. fæcalis alkaligenes* removed all the agglutination for *B. fæcalis alkaligenes.*

CASE 9.—A healthy Jewish girl of 26 played tennis throughout the day of Sept. 10th, which was hot and sunny. Shortly afterwards she complained of occipital headache and of feeling shivery, but for the next four days, although obviously ill and in spite of occasional vomiting and epistaxis (to which she was at times subject), she carried out her usual secretarial work. On Sept. 13th her temperature was found to be 101°, on the 14th it was 103°, and on the following day, when I first saw her in consultation with Dr. B. Herbert, it had risen to 105°. On the morning of Sept. 14th Dr. Herbert found a patch of dullness and faint breath sounds at the base of the right lung and was suspicious of early pneumonia, although he noticed that the respiration was not rapid and that the pulse-rate remained rather slow; it was recorded by a nurse as 104 to the minute, although it was nearer 120 during his examination. These slight signs at the right base cleared up in 24 hours, and Dr. Herbert asked me to see her, as the diagnosis remained doubtful. Her general condition was good, though she appeared seriously ill. She complained of occipital headache slight stiffness of the neck, and photophobia. Apart from trivial cervical rigidity and some sharp crepitations at the left base, physical examination yielded nothing of importance. In particular Kernig's sign was negative, the reflexes were normal, and the fundi were clear; there was no abdominal distension and the spleen was not palpable. There was no known tuberculosis in the family. The history of the onset—a steady rise in temperature, a slow pulse, headache and slight vomiting, and epistaxis—together with the discovery of crepitations at the left base (which had been preceded by questionable signs of early pneumonia on the right side), in the absence of splenic enlargement and any mental dullness, led me to suggest the possibility of psittacosis, although Dr. Herbert, who knew the family well, was fairly confident that contact with birds was unlikely.

Nevertheless, on inquiry we were told that on August 30th (11 days before the onset of illness) our patient's fiancé had made her a present of two love-birds, one of which at the time of purchase appeared to be off colour. The vendor, however, was confident that the bird would soon recover, but this cheerful prognosis proved to be incorrect, for it rapidly became worse and suffered from continuous diarrhœa; and a few days later, on the advice of a local bird fancier, it was placed in a separate cage apart from its mate. Despite the unpleasant nature of its disease, our patient continued to attend to the sick love-bird, and until she herself became ill no one else in the house did much for it; subsequently the bird was cared for by an elderly aunt (CASE 10), whose history is given below. The two love-birds, when Dr. Herbert and I inspected them, presented a remarkable contrast, for the sick one remained crouched and motionless on the floor of its cage with its feathers bedraggled and ruffled; its breathing was obviously laboured and it frequently passed loose stools. Surprisingly enough, it often took food voraciously. The girl and both birds were removed at once to the General Hospital, where the sick bird was found dead in its cage the next morning. The other bird remained healthy.

For the following week the patient was very gravely ill, with a high continuous temperature, which occasionally reached 106°, and was nearly always above 104°, despite frequent sponging. The pulse-rate remained about 120, but towards the end of the week reached 130. The respiration-rate was about 30 for the first three days, but later rose to 50 to the minute.

On Sept. 17th my colleague, Dr. K. D. Wilkinson, saw her with me in consultation, and we found a small area of consolidation at the left base. The remainder of the physical examination was negative, apart from the presence of a few seborrhœic spots on the chest. The patient told us that these always became more prominent at menstruation, which began that day and ran a normal course. She was still mentally clear, had slight cough with scanty muco-purulent expectoration, and complained of flatulence and difficulty in breathing. There was no abdominal distension. During the next three days she became progressively worse; mentally she was dull and torpid, but never completely stuporose, although at times there was mild delirium. The cough varied and rarely distressed her; in general she lay absolutely motionless with a curious impassive appearance which immediately suggested a comparison with Case 8, in whom this feature was much more prominent. This strange passivity (she was "highly strung" by temperament), in mild degree, persisted for some days after convalescence had begun. The signs in the lungs extended rapidly, and by Sept. 21st it was clear that both lower lobes were entirely consolidated; the percussion note was markedly impaired and tubular breath sounds were well heard over them. Respiration was rapid and shallow, and I think it is fair to say that most physicians at this stage would have been content with a diagnosis of lobar pneumonia if the history of the unusual onset and of the contact with the love-birds had not been available. The physical signs in the chest persisted unchanged for another two days; on the 21st a lung puncture was done on the right side for bacteriological purposes and about 3 c.cm. of rusty fluid was withdrawn from the pleura, but no more could be obtained. On the 23rd there was almost complete silence over the bases behind. The percussion note did not suggest fluid, and I believe that there was at this stage massive consolidation similar to that in Case 8. The breath sounds were faintly audible again on the 24th and were still tubular, but for the next two or three days the lower lobes were almost silent. Subsequently resolution took place fairly rapidly. On the 24th my colleague, Dr. Stanley Barnes, examined her and said that "she would do well for a Parkinson," a suggestion with which Dr. T. L. Hardy agreed when he saw her four days later. Throughout her illness the alimentary symptoms were slight. At one time there was unusual salivation—she seemed in her early torpid period to derive some comfort from constantly blowing bubbles of saliva from her lips—but this cleared up after four days. Distension was never marked, though she passed flatus freely; the stools were of a curious greenish colour and frequently loose. Vomiting occurred only very occasionally and she took nourishment well throughout. The urine remained normal. Apart from the curious parkinsonian appearance, no abnormal nervous signs were discovered. The same plan of treatment was followed in this case as had been tried in Case 8. On Sept. 19th and 20th she received two doses of serum from relatives who had been inoculated with T.A.B. vaccine on Sept. 10th. Neither of these injections had the slightest effect on her, and it seemed that insufficient time had elapsed to allow of the production of antibodies. The husband of the other patient (Case 8), who had been similarly inoculated on Sept. 7th, kindly allowed us to use his serum, and an intramuscular injection on the 21st of 7·5 c.cm. was followed by a drop of over three degrees in the temperature. After 36 hours the fever rose again to 104° and a similar injection was followed by a like result; further doses were given at daily intervals and appeared to bring the illness to a dramatic end some days earlier than might have been expected. The injections were prepared quite simply by allowing 20 c.cm. of the donor's blood to clot in a sterile tube, and as much serum as separated was used without any special treatment. Fresh blood was taken on each occasion for the following day's injection.

Bacteriological Report.—Neither sputum, urine, blood, nor fæces yielded any organism resembling *B. psittacosis*. Serum collected on Sept. 16th agglutinated both cultures of *B. psittacosis* (National Collection of Type Cultures) at 1 : 900 (not 1 : 1000) dilution, and also a broth culture of salmonella (Mutton) at 1 : 500 (not 1 : 700). An Oxford suspension of salmonella (Mutton) was agglutinated at 1 : 125. Negative results were obtained with salmonella (Newport), *B. dysenteriæ* (Gaertner), *B. typhosus*, and *B. paratyphosus* A and B. A later specimen of blood, taken Oct. 1st, failed to agglutinate broth cultures of *B. psittacosis*, salmonella (Mutton), or *B. fæcalis alkaligenes*, but agglutinated suspensions in saline solution of *B. psittacosis* 1 : 20, salmonella (Mutton) 1 : 40, and *B. fæcalis alkaligenes* 1 : 20. Saturation with *B. psittacosis* or with salmonella (Mutton) left the agglutination unchanged or even slightly improved for any one of the three organisms, but saturation with *B. fæcalis alkaligenes* removed all the agglutination for that organism and left it unchanged or improved for the other two. Serum collected on Nov. 8th, when the patient was convalescent, agglutinated similar suspensions of *B. psittacosis* and salmonella (Mutton) in rather higher dilution (up to 1 : 100) and an Oxford suspension of salmonella (Mutton) at 1 : 100. There was no agglutination with control normal serum.

CASE 10.—On Sept. 15th, 1929, as Dr. Herbert and I were leaving the house after our consultation on Case 9, we were told that the patient's aunt, who had cared for the sick lovebird for a few days, had become ill and had been sent to bed by her doctor with fever and bronchitis. She was admitted to the Selly Oak Hospital shortly afterwards with a slight temperature (about 100°) and signs of bronchitis and possible consolidation at the base of the right lung. As her condition did not appear grave and as her temperature soon fell to normal, she was transferred to the adjoining infirmary, but was brought back to the hospital when I told Mr. R. P. S. Kelman, the medical superintendent, of my suspicions of the possibility of psittacosis infection. Mr. Kelman was good enough to allow me to see this patient in the hospital on Sept. 21st. She was a feeble old lady of 73, with signs of emphysema and cardiovascular degeneration. A patch of consolidation was found at the right base, but her temperature was then normal; the respirations, however, were hurried—36 to the minute. Slight vaginal hæmorrhage of uncertain origin had occurred that morning and the urine contained albumin; nothing grossly wrong was found on pelvic examination. Dr. Hillier found that her blood serum agglutinated *B. psittacosis* strongly (up to 1 : 500 dilution) and she died a few days later, after developing a fresh patch of consolidation in the left axilla. No post-mortem examination was allowed. It is recognised that infections of the typhoid group in the elderly may follow an almost afebrile course, and in view of the history and positive agglutination this case may fairly be regarded as an instance of psittacosis.

CASE 11.—Dr. E. H. Alton of King's Norton, after reading my earlier communication on this subject, furnished me with the following account of a remarkable case that occurred in his practice.

Early in 1926 a middle-aged man returned to Birmingham from West Africa, bringing with him three young parrots, all of which, within a few days, sickened with diarrhœa and died. Almost immediately after the death of the last of the birds, the man himself, who had previously been in good health, became ill with continuous fever. At the end of a week he was seen in consultation by one of my colleagues at the General Hospital and a diagnosis of typhoid was suggested. A Widal test, however, proved negative. During the second week of illness extensive signs of pneumonia developed in the right lung, and he was again seen by the same consulting physician, who confirmed Dr. Alton's findings and thought the condition was probably due to an unusual influenzal infection. The fever persisted, and in the third week the man was almost continually unconscious. The physical signs in the right lung changed, and in place of well-marked tubular breathing the breath sounds became inaudible. Dr. Alton needled the chest several times, as he thought an effusion had developed, but never found fluid. He was so struck by the silence of the lung that he got his partner, Dr. J. A. Brown, to see the patient, and he also explored the chest with a negative result. The man died at about the end of the third week of illness. The spleen was never enlarged and there were no spots. At the time the possible significance of the contact with sick parrots was not appreciated, but the clinical history leaves no doubt that this was in fact a case of psittacosis.

CASE 12.—On Nov. 29th, in consultation with Dr. Smeeton Johnson, of Kidderminster, I saw, on three occasions, a man of middle age who had an illness that ran a course exactly similar to that of Cases 8 and 9, and my colleague, Dr. L. G. Parsons, who saw both these cases while they were in hospital and also Dr. Johnson's patient, agreed with me that they were clinically indistinguishable.

This man was a pigeon-fancier, and for years he had been daily in close contact with these birds, of which he had over a hundred in his own aviary. There was no definite history of contact with sick birds, but Prof. C. J. Lewis found that his blood gave a slightly positive agglutination for *B. psittacosis* and a negative result for all the other members of the typhoid and salmonella group; in addition the illness was brought to a dramatic end by the injection of serum from a man inoculated some weeks previously with T.A.B. vaccine, exactly as in Case 9. There was a history of a similar illness four or five years previously. The absence of sickness among any of the birds with which this patient was known to have come into contact raises the unpleasant possibility that this disease may be contracted from apparently healthy birds.

CASE 13.—On Nov. 23rd, 1929, a lady, aged 60, purchased a South American parrot which was noticed to be sick on its arrival in her home. The bird developed a nasal discharge, severe diarrhœa, and distressed breathing, and died on Dec. 8th. Two days later the lady herself became ill and was thought to have a cold. On the 13th her temperature was 104° and she had to stay in bed. I saw her first on Dec. 15th with Dr. W. J. Hirst, of Moseley. Her temperature was then 103°, but her pulse-rate was only 96. She complained of intense occipital headache radiating down the neck, but physical examination was quite negative, apart from the presence of a few scattered râles in the left lung. For the next two weeks she had a continuously high temperature, between 103° and 104°, and was often stuporose and completely incontinent. A troublesome cough was present throughout, without expectoration, and she had signs of diffuse bronchitis, but there was no definite consolidation. In the third week her temperature fell by lysis to normal for three days and her general condition improved slightly, but on the twenty-seventh day of her illness she relapsed and had a temperature varying between 99° and 101° for a fortnight; during this period there was definite consolidation at the right base. She now appears to be convalescent, but is mentally very emotional and unstable. Blood cultures taken on the fifth day of illness were sterile, and nothing of significance was recovered from the stools and urine in Prof. Lewis's laboratory. The agglutination reactions by Dr. E. Baylis Ash were as follows. On Dec. 15th (fifth day of illness) the reaction was completely negative to all the typhoid and salmonella group except *B. psittacosis* (Perry), with which there was a positive macroscopic result at a dilution 1 : 15 and microscopic 1 : 10. On Dec. 18th agglutination of *B. psittacosis* was present at 1 : 20 macroscopically and 1 : 40 microscopically. Salmonella (Mutton) was also agglutinated at 1 : 40 dilution, but all the others were still quite negative. On Jan. 17th (during the relapse) all the agglutination tests were quite negative.

Three small injections of serum from men inoculated with T.A.B. vaccine three months previously were given in the early stages of the illness and each was followed by a transient fall in the temperature, but it was not possible to arranged for continued treatment of this kind. In the later stages, after the positive agglutination results had been obtained, several daily injections were given of vaccine prepared from *B. psittacosis* cultures, but they had no influence on the disease.

CASE 14.—This patient was the husband of Case 13. On Dec. 17th, when his wife had been ill for one week, he received at my suggestion a prophylactic inoculation of T.A.B. vaccine (100 millions of each organism). Immediately afterwards he had intense pain at the site of injection, and an hour later had a rigor, vomited, and went to bed. For the next three weeks he had a moderate temperature (usually from 99° to 102°, but once reaching 104°), intense headache, and great prostration. The lower lobe of the right lung was consolidated one week after the onset of the illness, and there were signs of diffuse bronchitis, to which he had been subject for some years previously. Prof. W. H. Wynn saw him in consultation with Dr. Hirst and myself, and agreed with the diagnosis. *B. psittacosis* vaccine was also given in this case without effect. On Jan. 15th, when he was convalescent, his blood agglutinated salmonella (Mutton) (1·20 macroscopic and 1·40 microscopic) and *B. suipestifer* (1·20 macroscopic). Agglutination tests with all the other members of the typhoid and salmonella group (including *B. psittacosis*) were quite negative. This case ran a course exactly parallel with that of No. 7 of this series.

In connexion with these two cases it should be recorded that after the death of the first parrot a second similar bird was supplied by the dealer and placed in the same cage, which had been thoroughly scrubbed with lysol. This bird was taken to the University laboratory on Dec. 17th, and cultures were made from its nose and fæces with negative results. A few days later a nasal discharge developed, but there was no diarrhœa. The bird was killed on Dec. 20th, and a most exhaustive post-mortem examination showed that its condition was due to a streptococcal septicæmia. No non-lactose fermenting organisms were isolated from any of the organs and the parrot's blood failed to agglutinate the stock culture of *B. psittacosis* (Perry), and also the cocci isolated from the sputum of Case 14. It is clear that the illness of this parrot had no relation to the infection of the human cases.

A Second Group of Three Cases.

Cases 15, 16, and 17, all members of one family, were admitted to the General Hospital under my care at the request of Dr. Hugh Tibbits of Warwick. A parrot was bought on Dec. 19th, 1929, and died unexpectedly on Jan. 1st, 1930, without signs of previous illness apart from a questionable nasal discharge. Another parrot was obtained from the same dealer on Jan. 2nd, and this bird was noticed to be sick at the time of purchase and died on the following day.

CASE 15.—On Jan. 8th a woman of 51 complained of headache, drowsiness, and shivering, and she eventually had to take to her bed on the 12th. Dr. Tibbits saw her later and found signs of pneumonia, and sent her into hospital with the diagnosis of psittacosis on the 16th. On admission she was drowsy and apathetic; her temperature was 101° and the pulse-rate was about 100. The percussion note at the right base was dull, and breath sounds were entirely absent over the whole of the posterior aspect of the right lower lobe. Her temperature fell to normal in three days and remained so, except for trivial rises in the evening to about 99°, for a further four days, and her general condition improved. A few crepitations appeared in the silent area in the lung two days after admission, and breath sounds became audible. There was no cough or expectoration and no diarrhœa or vomiting. My house physician, Mr. Smallwood, found the spleen palpable on Jan. 22nd, but I could not feel it the following morning. A blood count showed a moderate leucocytosis (12,400 white cells with 83 per cent. polymorphonuclear leucocytes). Nothing of significance was recovered from cultures of the blood, urine, or fæces. Serum taken on Jan. 17th (the ninth day of illness) agglutinated *B. psittacosis* (Perry) strongly at 1 : 20 dilution and feebly at 1 : 50. There was also a feeble agglutination with salmonella (Mutton), but none with any of the typhoid or others of the salmonella group or with *B. fæcalis alkaligenes.*

CASE 16.—A man, aged 58, the husband of Case 15, was admitted on the same day as his wife—Jan. 16th. He had been ill for five days and almost constantly delirious for three. On admission he was excitable, mildly delirious, cyanosed, and obviously very ill. His temperature was 103°, his pulse-rate was 140, and there were signs of consolidation at the right base. He coughed a little, but there was no expectoration. The spleen was not palpable. The following day his general condition was worse; the right base was dull to percussion and breath sounds were absent; puncture of the chest yielded no fluid. A blood count showed a leucopenia (6000 white cells per c.mm.) A few hours later signs of consolidation were found in the left upper lobe and he died on the afternoon of Jan. 18th. There was no diarrhœa or vomiting. Cultures from the blood, fæces, and urine yielded nothing of significance, and there was no agglutination of any of the typhoid or salmonella group of organisms. A post-mortem examination was made 20 hours after death by Prof. G. Haswell Wilson; the following is the report:

"The body is that of a well-developed, somewhat obese man. There are no external morbid appearances. The pericardial sac is normal. The heart weighs 380 g. No lesion is found in the valves or cavities. The muscle is rather pale, but is not appreciably softened. The coronary arteries show slight patchy atheroma. The lungs are free from adhesions. A few minute petechial hæmorrhages are seen beneath the visceral pleura. There is no evidence of pleurisy except at the right base, where there is an area about half an inch in diameter covered by a thin pellicle of recent fibrinous exudate. The upper lobe of the left lung is completely consolidated, but the lung is not increased in size and is not marked by the ribs. The consolidated lung substance is of a dusky red colour and of a dry and almost crumbling consistence. There is no evidence of suppuration, and the appearances are quite unlike those of an ordinary lobar or broncho-pneumonia. The bronchi are congested and those of smaller size contain a small amount of turbid, blood-stained fluid, with no obvious muco-pus. The unconsolidated lung substance is poorly aerated, congested, and slightly œdematous. Similar changes are seen in the right lung, but on this side the consolidation involves part only of the lower lobe. At the edge of the consolidated area, just beneath the early fibrinous exudate on the pleura, there is a small area resembling ordinary broncho-pneumonia, with a small central bronchus from which muco-pus exudes on pressure.

"The peritoneum is normal. The liver, weighing 1500 g., is pale from cloudy swelling and slight fatty infiltration. The spleen, weighing 300 g., is enlarged and very soft. The pulp is intensely congested and is almost diffluent in consistence. The kidneys together weigh 300 g. The substance is pale from cloudy swelling and the appearance of the cortex suggests the presence of catarrh in the tubules. No lesion is found in the bladder. The suprarenals and pancreas are congested and rather soft. The stomach and intestines are œdematous. The mucous membrane of the stomach shows a few small recent erosions along the greater curvature. The small intestine contains a small amount of slimy, bile-stained material, but it is not congested, and there is no change in the lymph follicles. There is slight patchy congestion in the large intestine.

"The pia-arachnoid covering the cerebral hemispheres is opaque and slightly thickened and the underlying convolutions are slightly atrophied; otherwise no lesion is found in the brain or its membranes. The femur marrow is almost entirely fatty, but there is a small area of pale, very soft, red marrow.

"The changes in the lung are those of a pneumonia of unusual type and do not resemble those found in lobar pneumonia, in ordinary broncho-pneumonia, or in septic pneumonia complicating a septicæmia due to infection by any of the pyogenic organisms. The condition of the spleen, however, suggests that a septicæmia is present. There is no lesion to suggest typhoid fever or other acute enteric infection. In view of the changes found in the body I am of opinion: (1) that death was caused by pneumonia and septicæmia; (2) that the appearances are compatible with the clinical diagnosis of psittacosis."

A preliminary histological examination of the sections of the lung by Prof. Wilson shows that the affected areas are uniformly consolidated; the exudate is fibrinous, and that cells are relatively scanty and almost entirely mononuclear. There are scattered areas of congestion and hæmorrhage, and here and there small patches of œdema without fibrin. There is no selective perivascular or peribronchial distribution of the exudate, as occurs often in influenzal pneumonia. The smaller bronchi are filled with desquamated epithelium; the larger bronchi show a similar desquamation but are quite empty. A certain amount of anthracosis is present in the lung with a slight lymphatic reaction. A more detailed account of the histology is in course of preparation and will be included in a subsequent report.

An exhaustive bacteriological investigation of this case has been undertaken by Prof. C. J. Lewis and Dr. W. T. Hillier. A bacillus, in its sugar reactions resembling *B. fæcalis alkaligenes*, has been recovered from the lungs and spleen (both from cultures made at the post-mortem examination and from stab cultures made three hours after death). Prof. Lewis has also isolated from the lung another type of non-lactose fermenting bacillus, which he thinks may prove to be pathogenic. A complete report will be prepared as soon as possible.

CASE 17.—A man of 25, the son of Cases 15 and 16, was admitted to the General Hospital on Jan. 20th. He became ill on Jan. 16th with headache and diffuse pains about the body, but did not go to bed. There was no vomiting or diarrhœa. On admission his temperature was 105°, the pulse-rate 110, and the respiration-rate 25 per minute. He was torpid and slightly cyanosed and there were signs of consolidation of the right base, with marked tubular breath sounds. Two days later the affected lung was quite silent over the whole of its posterior aspect. Exploration yielded no fluid. On Jan. 24th a few fine crepitations were heard at the right base, but breath sounds were almost entirely absent; at the left base a large area of consolidation, with tubular breath sounds, was present posteriorly. Despite the extension of the pulmonary signs, the respiration-rate was only 24 per minute, and there was practically no cough or expectoration. His general condition has improved and his temperature has fallen by lysis to 101°. A blood-count showed a moderate leucocytosis (9800 white cells per c.mm. with 87 per cent. polymorphonuclear leucocytes). Cultures from the blood, urine, and fæces show nothing of importance. From the lung puncture a bacillus has been obtained similar to that isolated from the spleen and lung of Case 16. His serum does not agglutinate salmonella (Mutton) or *B. psittacosis* (Perry), but does agglutinate the organism recovered from the spleen of Case 16 at a dilution 1 : 40.

Four Additional Cases.

CASE 18.—That the clinical picture may be distinctive is shown by the fact that one of the nurses in charge of Cases 13 and 14 told me that she was sure that she had had a similar case some months previously, though at the time it had been regarded as typhoid. Dr. H. C. Rook, of Worcester, in reply to my inquiry, was good enough to send me the following account of the patient to whom the nurse referred :—

There is no doubt that the case brought to your notice was psittacosis. A lady, aged about 35, previously the subject of a hemithyroidectomy for Graves', bought a green Amazon parrot while on holiday at Exmouth toward the end of August, 1929. It immediately moped and was attended by her day and night until its death on Sept. 2nd.

I saw her on Sept. 4th (T. 101°, P. 90) with a history of two days' malaise. On the 8th (T. 102°, P. 100) there was a left-sided rub, and on the 9th, when I saw her with Dr. M. Campbell, of Droitwich, a small left effusion. A tentative diagnosis of typhoid was made, and with this a London consultant who saw her on the 10th agreed (T. 104·8°, P. 110). There was no rash and no enlargement of spleen. Blood count (10th): red 4,600,000, white 6300, and agglutination para. B. The bacteriologist said that he had never seen clumping occur so rapidly—dilution not stated. The temperature remained 104°–105° for a week and was not materially altered by cold baths, the first drop occurring 48 hours after a fixation abscess had been injected. During this time the patient was semi-conscious, with continuous delirium, pain in the neck muscles with head retraction, constipation, frequency and a highly acid urine with bacilli present in quantity. The abdomen was slightly tumid with tenderness over the descending colon, no splenic tenderness, and no rash. The pleuritic effusion, a thin layer, covered a large area; cough was constant with slightly blood-stained sputum. The pulse always remained lower than corresponded with the temperature in spite of the old-standing Graves's disease. Normally her pulse is 100–110. The tongue was brown and dry with sordes. The heart condition gave rise at times to considerable anxiety. The temperature fell by lysis with a corresponding amelioration of symptoms, and by Oct. 3rd the patient was well on the way to recovery.

CASES 19, 20, 21.—Dr. Coutts, of Dudley Port, has kindly provided me with the following account of three cases occurring in his practice.

In April, 1928, a parrot, obtained from a dealer, developed sickness and diarrhœa the day after its arrival in the house of one of his patients and died a few days later. In the house lived two adults and three boys then aged 11, 9, and 7, all of whom were perfectly well. Within a few days of the death of the parrot the eldest boy was seized with vomiting, diarrhœa, and abdominal pain. Profuse and repeated epistaxis occurred. The vomiting and diarrhœa lasted for a fortnight, and he also had signs of bronchitis and patchy broncho-pneumonia. His temperature was moderately raised. The total duration of illness was about eight weeks, and his condition for most of that time was serious. His subsequent health has not been good, as he is still liable to occasional attacks of abdominal pain. The two younger boys both had a similar illness, but milder in degree; the youngest was the least affected. They were taken ill within a week of the onset of the illness of the eldest. All the boys had handled the parrot, but the eldest had petted it most. Neither of the adults was affected.

Review of the Clinical Aspect.

With the four cases described in my first communication,[1] those now reported make a total of 21, of which five proved fatal.

It is fairly accurate to say of the severer cases that they resemble typhoid septicæmia in retaining a relatively slow pulse, despite a high continuous fever. Even before the development of the unusual pulmonary signs, however, certain features distinguish them from true typhoid; the onset is usually more sudden and the temperature rises more rapidly. Headache is intense, generally occipital, and often associated with slight cervical rigidity. Epistaxis occurred in one patient. Sweating was sometimes severe. Diarrhœa and vomiting sometimes occur in the early stages, but as a whole the alimentary symptoms, apart from distension, have been trivial, except in the case of the three children (Cases 19–21). The spleen became palpable in one case, and then only for a few hours; no rose spots have been observed. In one case a typhoid-like relapse occurred. The outstanding feature of the clinical picture is the involvement of the lungs. At the onset signs of slight shifting bronchitis appear, to be followed in a few days by those of extensive consolidation manifested by impairment of the percussion note and the presence of tubular breath sounds. Still later the percussion note becomes completely flat, and breath sounds in the affected area disappear. This curious silence of the lung may persist for some days after the temperature has fallen and the general condition has improved. A whole lung may be affected in this way. Resolution occurs very rapidly and completely, and is accompanied by fine crepitant râles. Repeated explorations of the chest had shown that these signs were in no way due to pleural effusion, and I concluded that they were associated with obstruction of the smaller bronchi. Confirmation of this opinion was afforded by the post-mortem of Case 16.

Certain negative features in the respiratory condition are important. Although cough is frequent and at times incessant, it is never painful, and expectoration is scanty and frequently absent; only twice was any rusty sputum obtained (Cases 5 and 18). Respiration is not hurried unless the area of lung involved is very extensive; it was easy and never "pneumonic" in character. Pleuritic friction was found only once.

The nervous signs described in Cases 8 and 9 are noteworthy, particularly as they were also marked in Case 12 and to a lesser degree in Cases 15 and 17.

Although the clinical course of most of the cases forms a fairly characteristic picture, it is clear from a review of the whole of them that the symptoms and signs may be but slight and equivocal—even when the disease proves fatal (Case 10)—and a diagnosis would be frankly impossible unless the history of contact with sick birds were elicited.

Ætiology of the Condition.

In our earlier investigations a review of such literature as was available led us to concentrate our attention on the discovery of an organism of the typhoid or salmonella type. In the first case, a bacillus corresponding fairly well with this group was recovered from a local parotid swelling, but it must be admitted that the identity of this organism was not completely established, as the importance of the matter was not then realised. Despite the exhaustive search that has been made in some subsequent cases neither *B. psittacosis* nor any similar organism has been recovered, either from a human patient or from a sick bird. This negative result, in agreement as it is with the work carried out at the London Hospital, favours the view put forward recently by Bedson and Western and Levy Simpson, that the disease may be due to a filtrable virus, and it cannot be denied that their recent communications[4] afford considerable experimental support for their suggestion. Prof. C. J. Lewis, however, has recently isolated from the cage of the parrots responsible for the infection of Cases 15, 16, and 17 an organism definitely identical with *B. psittacosis* and salmonella (Mutton). Experimental work with this organism is still in progress, but it has alre[illegible] been [illegible] that subcutaneous inoculation is [illegible] rs to a guinea-pig, and that a [illegible] injection has been followed by [illegible] within two days. This work of [illegible] dvisable, at the present stage, [illegible] as the [illegible] agent of infection, and certain other considerations in this connexion are important. In the first place, the clinical picture of the disease is extremely suggestive in many cases of a typhoid infection, and the incubation period, where it can satisfactorily be determined, is that of the typhoid group. Again, although too much reliance cannot be placed on these reactions, there is the definite fact that three cases gave a positive agglutination with organisms of the typhoid group (two to para. B., Cases 1 and 18, and one to *B. typhosus*, Case 5), and several others have given similar results with *B. psittacosis*—in three instances (Cases 8, 9, and 10) in high dilution. The post-mortem appearance of the lung (Case 16) is also suggestive of an infection by a non-pyogenic organism, and it will be interesting to see if a similar condition in animals or birds can be produced experimentally with the strain of *B. psittacosis* isolated by Prof. Lewis.

Finally, although the negative bacteriological results cannot be neglected, it must be remembered, as Tidy[6] has pointed out, that in epidemic human infection with the salmonella group the causal organism may only be recovered in a very small proportion of cases. For these reasons, therefore, I feel that the precise ætiology of psittacosis is not yet established, and that suggestive as is the work of Bedson and Western and Levy Simpson, it is still uncertain that the disease is entirely a virus infection.

An interesting point in our investigations has been the recovery of an organism resembling *B. fæcalis alkaligenes* from the lungs of Cases 8, 16, and 17. A similar organism was found independently in two laboratories in the heart blood, trachea, crop and bone-marrow of the love bird responsible for the infection of Cases 9 and 10, and also in the fæces of its mate. Feeding experiments with this organism did not give any evidence of toxicity with love birds proved to be free of it, but it may have some importance in association with *B. psittacosis* as a secondary invader.

Conclusion.

A critical survey of these cases leads almost inevitably to the conclusion that serious illness in man may be due to contact with sick parrots or love-birds. The history of Case 12 suggests that apparently healthy birds may also occasionally be responsible for human infection.

The exact means by which the disease is transmitted to man still remains obscure, and I have anxiously considered the possibility that the association with sick birds in these cases was nothing more than a strange coincidence. That facile explanation must, I think, be rejected for the following reasons: (1) The association of sick parrots with unusual forms of human illness was recognised 40 years ago, and a considerable number of cases of this type have since been reported at varying intervals from different parts of the world, though strangely enough very little attention has been given to the matter in this country. (2) The clinical course of the cases described conforms with none of the ordinary types of pneumonia, or typhoid, or infection with the salmonella group. (3) The post-mortem findings in Case 16 are suggestive of an unusual form of septicæmia with lung involvement of a distinctive character, which Prof. Haswell Wilson had not previously encountered. (4) The number of cases that have come to my notice seems to be too large to permit the hypothesis of coincidence and, as I have already said, since the publication of my first paper on this subject[1] a considerable number of histories of illness have been sent to me which warrant the opinion that they were in fact instances of this type of disease. Of these I have included five in this series.

In view of the predominance of the parrot as the agent of infection, the retention of the name "psittacosis" for this group of cases is justifiable at the present time, but is it correct to assume that it is a specific disease due to a particular micro-organism? The clinical similarity of the cases and the singular post-mortem findings suggest that it well may be, but certain considerations render a complete acceptance of that position impossible. Perry's investigation[4] showed that parrots might be heavily infected with an organism indistinguishable from salmonella (Mutton). It is this organism which is preserved in the National Collection of Type Cultures as *B. psittacosis.* So far as I am aware, no case of human infection followed contact with his birds, but obviously it was possible, and had it occurred the symptomatology might have been quite different from that recorded in my cases in which salmonella (Mutton) has not been found. There is, further, the result of the examination of the second parrot associated with Cases 13 and 14; in this instance the bird died of a streptococcal septicæmia, and human infection from it is a possibility which cannot be denied.

Finally, is psittacosis as rare a disease in this country as the scanty references in the literature suggest? The fact that cases have come to my notice at fairly regular intervals since my attention was first directed to the matter, and that Case 11 occurred in 1926, and Cases 19, 20, and 21 in 1928, strongly support the view that similar types of infection have prevailed in England, and that they have not been hitherto recognised.

DISABILITY FOLLOWING CERTAIN FRACTURES.[1]

BY A. J. COKKINIS, M.B. LOND., F.R.C.S. ENG.,

SURGICAL REGISTRAR, ST. MARY'S HOSPITAL; LATE SURGICAL REGISTRAR, ROYAL NATIONAL ORTHOPÆDIC HOSPITAL.

THE frequency of disability following fractures and the difficulties surrounding its treatment are too well known to require emphasis. Suffice it to say that no medical or surgical condition attracts more public notice, or figures more largely in the Press. It is frequently the cause of legal actions, the consequences of which may be disastrous to the medical men concerned.

From the practitioner's point of view the important problem is not the treatment of disability, but its prevention. This may be difficult or easy, but disability is very rarely inevitable. I propose to limit myself to fractures of the shoulder, the elbow, and the ankle, as these are particularly likely to be followed by disability. Colles's fracture is not included, for it forms the subject of a special study I am now engaged upon and the results of which I hope to publish in the near future.

Disabilities Following Fractures of the Shoulder.

Most cases of disability after fracture of the shoulder region are attributed either to adhesions or to osteo-arthritis. Injuries to the circumflex nerve, the brachial plexus, and the axillary vessels occur, but are comparatively infrequent.

Adhesions are exceedingly common and are responsible for much disability. Fractures of the shoulder are frequently treated with the arm bandaged to the side, a pad in the axilla, and the forearm supported in a sling across the chest, this fixation being maintained for two or three weeks before movements are begun. With such treatment, adhesions are almost bound to develop, particularly in or around the lower and front parts of the joint. These adhesions produce painful limitation of movement and interfere grossly with the function and usefulness of the joint. The movements mostly limited are abduction, external rotation, and, to a lesser degree, hyperextension of the arm. In fractures of the anatomical neck of the humerus or of the glenoid cavity of the scapula, the adhesions tend to be mainly intra-articular, and result from the organisation of blood clot in the joint or from the healing of tears in the synovial membrane or capsule. Both these fractures run into the shoulder-joint and the adhesions may be looked upon as natural consequences of the traumatic arthritis which ensues. The adhesions which follow fractures of the surgical neck of the humerus are mainly extra-articular, and result from the healing of tears of the capsular ligaments or of the muscles and tendons closely grouped around the joint. To enable the movement of abduction to occur, the lower part of the capsule of the joint is attached to the surgical instead of to the anatomical neck, thus securing for itself a certain necessary degree of looseness. In fracture through the surgical neck—which, by the way, is much the commonest fracture of the shoulder region—the lower part of the capsule is frequently torn. Unless special precautions are taken, the healing of this tear will be followed by contraction or adhesions in the lower part of the capsule, with the result that the movement of abduction becomes seriously limited. Abduction, which is the most necessary movement of the shoulder, is unfortunately also the weakest. It is lost with surprising ease, mainly owing to the development of adhesions, but also because it opposes gravity and is itself opposed by very powerful adductor muscles.

---

[1] Delivered before the Ilford Medical Society on Dec. 10th, 1929.

There should never be any difficulty in diagnosing adhesions following fractures of the shoulder. There is progressive limitation of movement in certain directions only, other movements remaining free. Attempts to obtain movement beyond what is permitted by the adhesions cause severe pain. The patient is unable to raise or turn his arm without pain, and soon loses confidence in, and becomes afraid of, using the joint. The organic disability thus becomes aggravated by functional weakness, and the latter may persist even when ful movement has been restored by treatment.

In all cases absorption of hæmorrhagic exudate should be hastened by early massage, perhaps coupled with radiant heat. When the fracture is incomplete or soundly impacted, as is often the case with the anatomical neck, adhesions can be completely prevented by early mobilisation. Gentle, supported passive movements are commenced on the third or fourth day and are gradually increased until by the end of the week the arm is abducted to a right angle. The movements should be performed by the practitioner himself, and to ensure that the abduction is not the result of rotation of the scapula, this should be controlled by an assistant. In these cases the only support which is necessary is an efficiently applied sling, which is removed once or twice daily for the exercises.

When the fracture is complete, early mobilisation is unfortunately impracticable owing to the danger of causing redisplacement. It is always possible, however, to reduce the adhesions—and the disability occasioned by them—to a negligible minimum, by supporting the shoulder in abduction during the fixation stage (three weeks). For this purpose either a skeleton abduction splint or a plaster-of-Paris spica may be used. Incidentally, this position usually secures far better alignment of the fragments than can be obtained with the arm at the side. In this position of abduction, effective adhesions can only form in and around the upper part of the joint, and these will be readily stretched by the weight of the arm when the limb is brought down again.

At an early stage the adhesions can be stretched and the lost movements regained by systematic exercises, but the process tends to be long and tedious and, unless due care is taken, there is danger of fracturing the young callus and of causing repeated trauma which may terminate in osteo-arthritis. When a reasonable trial of exercises fails to restore mobility, the adhesions must be broken down by manipulation under anæsthesia, sufficient time (10 to 12 weeks) having first been allowed for the consolidation of the fracture.

Osteo-arthritis is a common complication of fractures of the shoulder in middle-aged and elderly people, and is especially likely to follow fractures of the anatomical neck of the humerus. Its development is a sequel to trauma of the joint, particularly when there is unreduced displacement of the articular surfaces and rough ends project into the joint cavity. Osteo-arthritis of the shoulder causes much pain and stiffness, both of which are aggravated after rest. Abduction is again the movement mostly limited. Creaking can be felt over the joint on movement, and there is usually a characteristic X ray picture.

Absolute reduction of displacement and restoration of smooth intra-articular surfaces is the ideal prophylactic measure, but unfortunately this is not always practicable. Much can be done to alleviate the symptoms by physical measures, such as avoidance of strain, massage and careful exercises, diathermy and radiant heat. Foci of infection must be looked for and treated. Very often, however, these measures fail to give adequate relief, and we have to resort to excision of the head of the humerus to overcome the disability. The results of this operation are usually quite satisfactory.

Disability Following Fractures of the Elbow.

In this group are included fractures of the lower end of the humerus, the upper end of the radius, and the coronoid process of the ulna. Disability after these fractures is mostly produced by the following complications: stiffness of the elbow, ischæmic contraction, injury to the ulnar nerve, and myositis ossificans. Malunion, with alteration of the carrying angle, is another cause of disability, but can be easily avoided by securing accurate reduction of the fracture.

Stiffness of the Elbow.—Disability from a stiff elbow is a very frequent result of fractures of this region. The limitation of movement may be produced by adhesions or by excessive callus formation and can usually be attributed to faulty after-treatment. Modern teaching rightly insists that these fractures after any displacement is reduced should be put up with the elbow in full supination and in as much flexion as is consistent with a free circulation. There is much difference of opinion, however, on the subsequent treatment. The usual procedure is to remove the sling or retentive bandage once daily, after the fourth or fifth day, for massage and active extension of the elbow to the limit of painlessness. The range of movement is increased daily, full extension being aimed at by the end of the third week. Theoretically this method of treatment should be above criticism, but its practical results are often most unsatisfactory. The elbow is an exceptional joint in that early mobilisation, instead of preventing stiffness, actually seems to predispose to it. I think the explanation is to be found in the marked and well-known tendency for excessive callus to be formed in this region. Early movement naturally throws a strain on the young callus and leads to further overgrowth of it. The eventual result is a progressive limitation of movement, especially of flexion, although for the first few weeks a good range of movement may be obtained. Further damage is often inflicted by the misguided zeal of energetic masseuses who, in the erroneous hope of dispersing adhesions, actually produce them by the so-called petrissage or deep kneading variety of massage. This traumatises the young fibrocellular tissues thrown out in the process of repair, and thus leads to fibrosis and scarring in and around the joint.

Confronted by a progressively stiffening elbow, which seems to become worse the longer massage and exercises are continued, the practitioner often falls into the error of trying to mobilise the joint by forcible manipulation under an anæsthetic. This may improve matters for the moment, but the elbow is curiously intolerant of such treatment, and the ultimate result is more callus, more adhesions, and worse stiffness. Occasionally even absolute ankylosis may follow.

This unfortunate experience is leading to the recognition that fractures of the elbow should be treated by a prolonged period of complete immobilisation in flexion and supination. This may be carried out by loops of adhesive plaster or by a "figure of eight" plaster-of-Paris bandage. Three weeks is the period recommended by many orthopædic surgeons, but in my opinion four weeks would not be too long. The elbow, of course, is the only joint immobilised, the shoulder, wrist, and hand being moved from the first. Massage should be avoided absolutely. At the end of the four weeks the retentive appliance is removed, the arm supported by a sling, and gentle active movements commenced. After another fortnight the patient is encouraged to use the limb and the sling is discarded. The elbow will be rather stiff at first, but the movement which will be limited is extension, and it is surprising how easily this stiffness is worked off with functional use, especially in children, who form a large percentage of the patients. My experience has convinced me beyond any doubt that prolonged immobilisation followed by functional use is the correct treatment for these fractures. Its adoption, however, requires a little courage, for the surgeon will have to resist not only his own instinct, which will urge him to employ the measures he has found effective in other fractures, but also the demands of the patient, and especially of the parents, who may not unnaturally consider the treatment old-fashioned and its immediate results disappointing. The ultimate result, however, will more than justify these measures.

Ischæmic contraction is one of the worst disasters that can result from faulty treatment. It is a common complication of fractures of the elbow only, and is caused by tight splinting or bandaging. Nowadays, the cases usually follow fixation of the elbow in acute flexion, without allowance for the post-traumatic œdema which follows the fracture. Children are more liable than adults, because their complaints of pain or tightness are apt to be ignored and also because their arteries are more compressible. The first symptom of the condition is pain, which is complained of within a few hours of the constriction. This is rapidly followed by swelling, coldness, and blueness of the hand. Within 24 hours the characteristic deformity, known as Volkmann's contracture, has made its appearance. The elbow is flexed, the wrist flexed and pronated, and the fingers clawed into the palm. On removal of the splints or bandage the muscles of the front of the forearm are felt to be hard and doughy, while active movements are markedly diminished and it is impossible to extend the fingers and wrist. Occasionally there is a glove-like anæsthesia of the hand and fingers. Pathologically the condition is an ischæmic myositis, and results when the muscles have been subjected to a partial but prolonged deprivation of their blood-supply The affected muscles first become œdematous and, unless the constriction is rapidly removed, they undergo a kind of coagulation-neurosis and very soon become doughy, shortened, and paralysed. An interstitial fibrosis follows and matts the muscle-bellies into a firm inextensible mass. The resulting disability is often absolutely crippling, and in neglected cases the ultimate outlook is extremely bad.

Ischæmic myositis is a condition which need never occur if reasonable precautions are taken. When splints are used they should be well padded, while bandaging should never be tight. Ample allowance must be made for post-traumatic œdema and, above all, fractures of the elbow should never be put up in acute flexion before the œdema has subsided. A comfortable degree of flexion (130° to 140°) is all that is necessary at first. A careful watch should be kept on the pulse, and at the first complaint of pain or constriction or the first sign of swelling, coldness, or blueness of the hand the splints or bandage must be removed and the limb massaged and moved.

Once the contracture is established, chief reliance must be placed on passive stretching of the contracted structures. The distal joints are straightened first, starting with the fingers, the proximal joints being flexed to relax the shortened muscles. The ground gained is preserved by splinting, further splints being superimposed as more proximal joints are extended until all tendency to contraction has been overcome. If these measures fail, some benefit may be expected from operation, but the ultimate results are usually poor, as the fibrosed muscles can never recover normal function.

Myositis Ossificans.—The traumatic variety of myositis ossificans is an uncommon but important cause of disability after fractures of the elbow. The fractures are usually incomplete, the periosteum being torn and bone cells escaping into the muscle-tissues. As a result masses of true bone form, mostly in the substance of the brachialis anticus, and cause considerable pain and weakness, besides interfering to a degree with the movements of the joint. These masses can be easily recognised in a radiogram. If the cases were left alone the condition would soon subside and the ultimate disability would be nil. But unfortunately the lesion is often aggravated by injudicious physical therapy, especially by deep massage and forcible movements. The result of such treatment is to provoke a reaction of the osteogenetic tissues and a further escape of bone cells, until quite large masses of bone may be formed, with progressive disability as the ultimate outcome. This, then, is another argument in favour of prolonged immobilisation and against the use of massage and early movements in fractures of the elbow.

Injuries of the Ulnar Nerve.—The ulnar nerve is mostly injured in fractures involving the internal condyle of the humerus. In the great majority of cases the nerve injury is actually coincident with the fracture and is caused by the original violence and not by the fracture itself. This applies not only to the ulnar nerve but also to all nerve injuries complicating fractures. Secondary involvement of a nerve by a perineural fibrosis or by the friction effect of callus does occasionally occur, but is very much less common. The belief that nerve injury is produced by a nerve being caught in and compressed by callus is absolutely erroneous, although it may be comforting to the practitioner who has overlooked a nerve lesion existing from the first, and who only discovers it when the splints have been removed and functional use of the limb resumed. Safety can only lie in strict observance of the rule that all cases of fracture should be investigated for a possible nerve injury at the very first.

Disability Following Fractures of the Ankle.

No fractures are responsible for more disability than those of the ankle. Bad results are, in fact, so common that a feeling exists among many practitioners that a degree of disability is inevitable after these fractures. This, in my opinion, is quite an unjustifiable attitude to adopt. Admittedly, the treatment of fractured ankle is characterised by peculiar difficulties, but it is perhaps not adequately realised that all these difficulties can be overcome, and that it is possible to obtain very satisfactory results in the vast majority, if not in all cases, provided certain essential principles of treatment are scrupulously observed. Nearly all cases of disability can be attributed to one of three complications: gross malunion, traumatic flat-foot, and osteo-arthritis. It can be stated quite emphatically that all these causes of disability are directly or indirectly caused by errors of treatment, and therefore that they can all be prevented.

Gross malunion occurs after fractures with marked displacement, which have either been neglected or treated very inefficiently; these cases are becoming much less common. Many patients with gross deformity after a fractured ankle retain remarkably good mobility of the ankle and tarsal joints, others develop a stiff and painful ankle, but they all complain of weakness and instability and find walking difficult. To prevent malunion it is necessary to secure absolute reduction of every element of displacement at the first. Fractures of the ankle vary considerably in their ætiology and in the resulting displacement. In the great majority of cases the essential injury is a fracture of the lower end of the fibula caused by violent abduction or external torsion of the foot. The fracture may be transverse and occur a little above the external malleolus, but more often it is oblique and runs through the malleolus itself and into the joint. In some of these cases the fracture of the fibula is uncomplicated, the tibia and ligaments remaining intact, without any displacement. More frequently, however, the internal lateral ligament is ruptured or the internal malleolus is avulsed by a more severe degree of violence. In these cases the lower end of the fibula, with the foot, are displaced outwards into a valgus position, and there is frequently some overlapping of the fragments, with shortening of the fibula. Occasionally there is marked backward displacement of the foot in addition, but this is generally caused by an associated fracture of the posterior margin of the lower end of the tibia.

No matter how severe the displacement, accurate reduction can nearly always be obtained by manipulation under an anæsthetic. The essential steps in the technique are as follows:—

The knee is first flexed to relax the tendo Achillis. The surgeon then grasps the foot with one hand and the leg with the other, and very deliberately corrects every element of displacement. *In the usual case of fracture with outward* displacement the foot should be forcibly pulled down, and then twisted inwards until the astragalus is brought completely under the lower end of the tibia. Definite contact must be made between the astragalus and the internal malleolus. In this manner the outward displacement is corrected and the fibula realigned and restored in length. It is this realignment of the fibula which is the essential step in the reduction of the fracture. In addition, any backward displacement must be corrected by pulling the heel forwards until full dorsiflexion of the ankle is obtained.

The crucial part of the treatment lies in the fixation of the limb in a retentive apparatus, without allowing redisplacement to occur. Actually the danger of this is exaggerated, but undoubtedly the safest thing to do is to apply a three-piece sectional plaster case, which completely overcomes the risk of redisplacement. First the foot and then the leg are encased in plaster bandages, a two- or three-inch interval being left at the fracture site. When the leg and foot pieces have hardened, the third piece of plaster is applied by an assistant, while the surgeon holds the foot in full inversion and slight dorsiflexion. Great care must be taken to prevent circulatory embarrassment by adequate padding, and it may be necessary to remove the first plaster after the œdema has subsided and apply a fresh and closer-fitting case. In three weeks the plaster is removed, a light bivalved case is applied, and movements started. Excellent reduction can be obtained by the above technique, even in fractures with gross displacement. Six months after the fracture the functions of this patient's ankle and foot were absolutely normal.

Traumatic flat-foot is an exceedingly common result of fractures of the ankle. Although predisposed to by shortening of the fibula, the main cause is premature and unguarded weight-bearing, which has the effect of causing the young callus to yield and so leads to progressive valgoid displacement of the foot. This variety of flat-foot is curiously painful and rigid, and causes very severe disability. At first the rigidity is produced by muscle-spasm, but it becomes fixed later by the formation of adhesions.

Fortunately, the prevention of traumatic flat-foot is a simple matter; the essential point is to prohibit any weight-bearing until the end of the second month. For the first six months after this protection should be afforded by wedging up the inner border of the shoe by one-third to half an inch, while in heavy people an outside iron with inside T-strap is recommended in addition. Either boots or strong shoes should be worn for the first few months. When flat-foot is an accomplished fact it is best treated by thorough mobilisation under an anæsthetic, the object being to break down adhesions and restore the arches of the foot. For a few weeks the correction should be maintained by encasing the foot in a bivalved plaster in full inversion. After this the patient is allowed up with a thickened inner border of the shoe and a long arch support, mobility of the joints being preserved by massage and exercises.

Osteo-arthritis can be attributed to incomplete reduction of displacement. The joint-line is broken and rough ends project into and irritate the joint, and osteo-arthritis is the result. The older the patient the greater is the likelihood of osteo-arthritis. The ankle becomes swollen, stiff, and very painful, the patient being severely disabled.

The prevention of osteo-arthritis depends entirely on securing absolute reduction of displacement, which must in all cases be immediately confirmed by X rays. If the radiogram shows any residual displacement, it is wiser to obtain exact anatomical reduction by open operation than to leave things to nature.

Clinical and Laboratory Notes.

A CASE OF ANEURYSM OF THE HEART.

By W. S. Russell Thomas, M.B. Camb.

The following case presents some interesting features.

A fairly stout man, aged 58, died suddenly after defæcation. He had not consulted a doctor for years, and, according to his wife, the only complaint she had heard him make about his health was of some shortness of breath and occasional pain over his heart.

Post-mortem examination revealed a distended pericardium, containing a very large quantity of blood. The heart was removed very carefully. It was larger than normal, and there was a good deal of fatty infiltration, but the most striking feature was an obviously thin-walled sacculation, bigger than the half of a walnut shell, on the anterolateral side of the left ventricle. On the superior part of this sacculation was a ragged hole through which a pencil could be passed.

The mitral and aortic valves were slightly thickened and the left ventricle dilated, with walls somewhat thickened at the base, but rapidly thinning towards the apex. The thickness of the walls above the sacculation was about one-eighth of an inch; at the sacculation only the thickness *of the membranes of a fœtus*, and nearer the apex they became slightly thicker, but not more than one-eighth of an inch. The myocardium showed definite signs of fatty degeneration, and the aorta some patches of atheroma; otherwise there was nothing abnormal.

The other organs were in fair condition except for one stone in the gall-bladder, and what appeared to be a small quantity of pus in the pelvis of the right kidney; the kidney substance was almost normal.

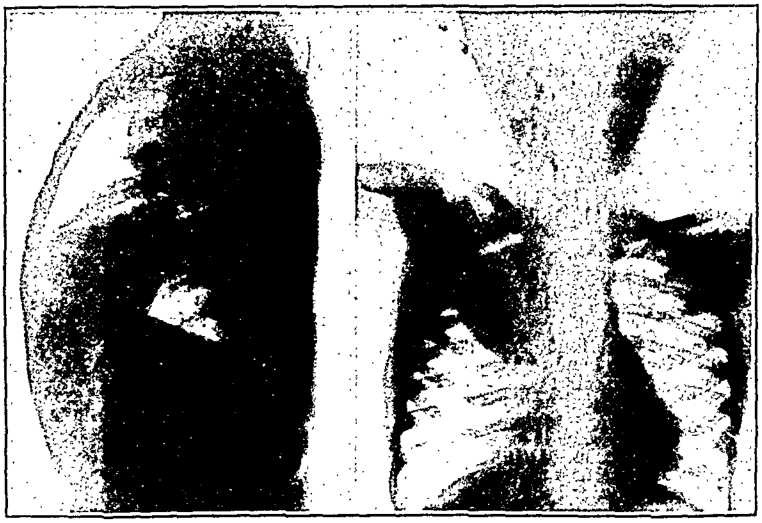
Here, then, was a man with an extremely thin-walled left ventricle—so thin in one part that it formed a very marked sacculation—yet feeling well enough to work. His symptoms were not sufficient to make him want to consult a doctor. One day the sacculation became so thin that it burst after the act of defæcation, and death followed almost immediately.

CASE OF
GANGLIONIC NEUROMA OF THE MEDIASTINUM IN A CHILD AGED NINE.

By W. C. Harvey, M.D. Glasg., D.P.H.,
MEDICAL SUPERINTENDENT, DUMFRIES AND GALLOWAY SANATORIUM, LOCHMABEN.

The following are some notes on a rather unusual and interesting case which was recently admitted to the Dumfries and Galloway Sanatorium, Lochmaben, for observation purposes.

A child, aged 9 years, was said to have been quite well until May, 1928, when she developed broncho-pneumonia. After her recovery from this she was left with a p [illegible] ugh which was worse at night, and in addition she suffered from night sweats and an apparently genuine lassitude. At times she became very breathless and cyanosed and was absent from school for prolonged periods. At other times she would be almost free from symptoms. After a period during which she did not improve, the family doctor called in the tuberculosis officer for Kircudbrightshire, in which county the child resided. Tuberculosis was rightly suspected, and the sputum, which was occasionally copious, was examined. No tubercle bacilli were found, but there was an increase of albumin in the sputum and it was therefore decided to send her to the sanatorium for a period of observation. She was accordingly admitted to Lochmaben on July 7th, 1929.



Lateral and anterior radiograms of the chest, showing position of the tumour. In the films the border of the lung could be traced through it—i.e., the tumour projected beyond the lung on all aspects.

The child was well-nourished and looked quite healthy apart from a rather marked sallowness of the skin. Physical examination of the chest revealed a pronounced dullness over the upper lobe of the right lung and in this area the breath sounds were considerably diminished posteriorly, but were bronchial in nature in front. No adventitious sounds were audible at any time and there was no marked change in vocal resonance. The child's voice was harsher than normal. She was observed over a short period and the temperature was found to be perfectly normal, while the pulse-rate was quite steady. The Pirquet test was mildly positive.

An X ray film of the chest was taken and revealed a most peculiar condition. A large mass, of a circular shape and with a well-defined margin, was seen to be filling up the whole of the upper lobe of the right lung. The mass was contiguous as far as could be seen, with the chest wall dorsally, and was causing a "kinking" of the trachea. It was very difficult to tell from the radiogram whether the mass was extra- or intra-pulmonary in origin, and the film was accordingly sent to Dr. Woodburn Morrison, radiologist, Royal Infirmary, Edinburgh, for his opinion. Dr. Morrison sent back word that he could not make up his mind on the point in question, and suggested that the child should be sent to Edinburgh for further investigation. This was done and a diagnostic pneumothorax was performed. Further radiograms (see Figures) revealed the fact that the mass was extra-pulmonary and quite free from the chest wall. The provisional diagnosis of a cyst, either dermoid or hydatid, was made and permission to operate was obtained, the child then being handed over to Mr. Bruce Dick for operation.

On Oct. 26th Mr. Dick, under local anæsthesia, removed about one inch of the second and third ribs posteriorly, fixed together the visceral and parietal pleura in the neighbourhood and made a preliminary investigation of the mass. Rather to everyone's surprise it was discovered to be a tumour of a lipomatous nature situated outside the lung and completely encapsulated. The wound was then stitched up and the child left for a week. Seven days later the wound was reopened under a general anæsthetic for the removal of the tumour. The removal was not easy, as the tumour was large and had a small pedicle attached to the mediastinum. Eventually, however, it was removed successfully after being freed from its capsule. The child ran a temperature for a few days, but after that she made an uninterrupted recovery and within three weeks of the operation was up and about and ready to go home. Further radiograms have shown that the lung has fully re-expanded. A certain harshness of the voice which was present before the operation disappeared.

The sections of the tumour showed that it was composed of ganglionic nerve-cells and non-myelated nerve-fibres. The stroma consisted mainly of fatty tissue.

As there are very few cases of mediastinal tumours of this nature on record, this one appears to have some interest. A feature of the case was the difficulty in diagnosis since the symptoms and, to a certain extent, the signs simulated hilar tuberculosis rather closely. Indeed, even when tuberculosis had been excluded, the diagnosis was not finally cleared up until exploratory thoracotomy was performed.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 8TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 374 (last week 354); scarlet fever, 2727; diphtheria, 1975; enteric fever, 34; pneumonia, 1332; puerperal fever, 45; puerperal pyrexia, 111; cerebro-spinal fever, 9; acute poliomyelitis, 12; encephalitis lethargica, 20; dysentery, 12; ophthalmia neonatorum, 87. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Feb. 11th–12th was as follows:—Small-pox, 571 under treatment, 26 under observation (last week 558 and 28 respectively); scarlet fever, 2310; diphtheria, 2786; enteric fever, 16; measles, 1003; whooping-cough, 95; puerperal fever, 22 (plus 13 babies); encephalitis lethargica, 120; other diseases, 15. At St. Margaret's Hospital there were 12 babies (plus 3 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox or enteric fever, 76 (32) from measles, 12 (2) from scarlet fever, 31 (6) from whooping-cough, 61 (12) from diphtheria, 60 (18) from diarrhœa and enteritis under two years, and 89 (18) from influenza. The figures in parentheses are those for London itself.

Fatal cases of measles were concentrated at Manchester 10, Portsmouth 9, West Ham 8. Deaths from whooping-cough were much more widely distributed, with a maximum of 4 at Bradford. Diphtheria claimed 7 victims at Liverpool and 4 at Cardiff. No great town recorded more than 3 deaths from influenza.

The number of stillbirths notified during the week was 302 (corresponding to a rate of 45 per 1000 births), including 50 in London.

COUNTY NURSING ASSOCIATIONS.—At a meeting of the Committee of the County Nursing Associations last week those bodies were recommended to apply to the new Public Assistance Committees for the continuance of the grants hitherto given by boards of guardians for the nursing of necessitous cases. An inquiry is being made into the schemes adopted by hospital leagues to provide hospital treatment for their members with the view of adapting them to the district nursing service in the hope of lessening the pressure on the hospitals.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF THERAPEUTICS AND PHARMACOLOGY.

A MEETING of this Section on Feb. 11th, with Dr. GEORGE GRAHAM in the chair, was devoted to a discussion on the

TREATMENT OF URÆMIA.

Prof. F. G. LANGMEAD, in opening, said that, so far as the physician was concerned, uræmia as met with in Bright's disease was a late symptom of an incurable disease, and for that reason did not provide very hopeful material for a talk on treatment. But various views were held on what ought to be understood by the term uræmia; one school allocated to it a small group of symptoms—chiefly cerebral and gastro-intestinal—whereas another school would include any uræmia which could be attributed to toxæmia, even renal retinitis. The treatment could not be approached scientifically without knowledge of its cause, and at present knowledge could not be said to have got beyond the stage of hypothesis. If uræmia was to be regarded as a toxicosis limited to Bright's disease, it must be inquired whence the toxins were derived, whether from katabolic processes or from the kidneys themselves; whether the ductless glands, such as the adrenals, played a part; and whether the presence of toxins preceded the renal disease and explained its production. It was possible that several factors combined to form the picture which received the label uræmia. Here lay a vast field urgently needing exploration, and until it had been explored the treatment must be largely empirical. Really, the proper treatment was to prevent the onset of uræmia, and this meant greater care of the patient in respect of specific infections and the elimination of focal sepsis. The speaker's own usual treatment of uræmia had, he said, no flavour of novelty; it consisted of purgation, diaphoresis, and venesection—the latter being the greatest of the three. There was need for care in purgation and his preference was for jalap, which acted quickly as a cathartic, and was, he thought, preferable to salines. For diaphoresis he had no hesitation in combining hot packs or radiant heat baths with pilocarpine if the patient had no heart trouble or symptoms of respiratory failure. Hot beverages, such as lemonade, enhanced the prospects of profuse sweating, which was of great benefit in these cases. He had seen patients come out of uræmic coma as a result of profuse sweating, but he was aware that the use of both pilocarpine and fluids was open to dispute on theoretical grounds. Another bone of contention was the use of morphia. He gave this drug when there were twitchings and convulsions. In dogs it was found that injection of morphia increased the diuresis if that were already present. On the other side was the possibility of provoking distension of the colon. Some thought lumbar puncture dangerous in the presence of uræmia, but Prof. Langmead had seen benefit from its use, and some physicians *preferred it to other methods*. The diuretics which seemed permissible were the saline group, though perhaps even those were better avoided. Diuretics containing mercury seemed to be distinctly dangerous. Isotonic salines apparently threw an increased burden on the kidney and hypertonic salines had an added disadvantage. The injection of a 5 per cent. glucose solution might prevent some of the disadvantages; Strauss reported increased diuresis with it, but the speaker did not think *Strauss used it in uræmia. He had himself* given it to a patient with a large white kidney and considerable œdema, which had been present some months and had failed to react to the usual treatments, and as a result the patient was much brighter, considerable drowsiness having come on a short time previously. He would like to know whether cupping and the use of hot rectal salines had gone out of use; he did not know how they acted, unless it was by reflex dilatation of the splanchnic vessels.

Uræmia was accompanied by deficiency of calcium in the blood, and this had led to the use of parathyroid and calcium lactate. He asked whether those who had used this had had any effect from *it other than increase of the blood calcium.* Were any tangible effects on record as a result of using alkalis in uræmia? Also had any of his hearers carried out blood-washing—i.e., removing toxins from the blood by dialysis? The method was to remove 500 c.cm. of blood at a time, using heparin to prevent coagulation, dialyse it through a collodion membrane, and then return it to the body, the process being repeated until most of the blood had been so treated. By this means 1·75 g. of urea had been removed, *but the result in the classical case had been* no more than a week's improvement. The chief use of operation in uræmia, on the medical side, was in acute cases with suppression, in which acute congestion and consequent tension in the capsule interfered with function; incision of the capsule then permitted of a freer renal circulation. The opportunities for this operation were rare, but he had known it done with some success in mercurial nephritis. Thyroid extract had been used to promote diuresis, but as it enhanced metabolism he did not think it should be employed in uræmia.

Dr. E. P. POULTON asked why Prof. Langmead gave a 5 per cent. glucose solution as a hypertonic rather than 6 per cent. or 7 per cent. With regard to the use of parathyroid, he said that all last summer he had had under care a man with what would be called large white kidneys. Parathormone was tried in big doses, and the first time it was used it seemed to have some effect in diminishing the œdema and increasing the *flow of urine. Then it was stopped. On a second* trial in the same patient it was not successful. The calcium was slightly raised as a result, but was still low. What produced the most dramatic effect was the ordinary administration of urea. 15 g. thrice daily raised the blood-urea to 40 or 50 mg. and the urine was increased from 500 c.cm. per day to 1500. He had read that if potassium and calcium were given together they produced diuresis in the isolated kidney.

Low Protein Diet.

For uræmia Dr. Poulton thought a low protein diet should be given, and one of two cases recently under his care illustrated its value.

A woman, aged 54, had suffered from headaches for three years. Her feet and arms were swollen, and two days before the note was made she began to vomit; during the previous three weeks she had not passed the usual volume of urine though drinking her accustomed amount. Her blood pressure was 165/120 and her blood-urea 90. She had 16 g. *of fat and 24 g. of carbohydrate,* and *two days later the* blood pressure was 160/110. She was then put on a strict diet with hardly any protein, being fed on vegetables, potatoes, fruit, butter, and copious drinks of dextrose. The blood pressures on the three following days were 140/90, 140/81, and 142/80. The last blood-urea estimation was 53.

Care had to be taken that the amount of albumin lost was made up by the diet. The other case was not successful, but it bore out certain points. Primarily it was one of *Bacillus coli* pyelitis, and in spite of treatment this grew worse, so that the condition was now probably "surgical kidney." When she entered hospital the blood pressure was 230/135, the blood-urea was 280 mg., and she was vomiting. She was put on a fairly high protein diet for a time, and was then started on a new diet, containing almost no protein. Yet the blood-urea increased daily, the figures being 291, 320, 309 (cerebro-spinal fluid), and 394. She was passing 25 parts of albumin per 1000. The volume of urine was 18 oz. a day, and it contained 1 per cent. urea. He wondered where all this increase *came from, seeing* that the diet contained practically none. Did it mean that the body proteins were breaking down in the last attack?

Dr. W. LANGDON BROWN thought the gastro-intestinal disturbance in these cases showed an attempt was being made on the part of the body to get rid of some of the nitrogenous waste. The vomited material contained a large amount of ammonium salts. The skin rashes, too, were an alternative method of excretion; these he had seen in cases with very high blood-urea.

Classification and Treatment.

He personally would include under the term uræmia three groups: (1) those cases with convulsions and amaurosis; (2) those with uræmic asthma; and (3) those with all the other cerebral manifestations which were familiar. The first group he thought were due to some general toxic condition, in which the kidney might not share, because they were encountered in such conditions as eclampsia and in the degenerative toxæmic kidney. Though alarming and dramatic, convulsions were amenable to treatment, and often stopped after venesection, patients sometimes recovering thereafter from the nephritis as well as the uræmia. During the war he had eight cases with uræmic convulsions. None of them died, and scarcely any of them left hospital with any albuminuria. Therefore these cases were not necessarily associated with damage to the kidney. It was agreed that uræmic asthma was associated with acidæmia due to the retention of acid potassium phosphate, and here help was derived from the free administration of alkalis. The third group were associated with a rise of blood-urea. The uræmia was certainly not due to the retention of urea; probably the culprit was some amino-acid. The figures given by Dr Poulton suggested that in the last resort there was a breakdown of nitrogenous protein.

As to treatment, he differed from the opener in that he did not like pilocarpine When he used it earlier in his career, respiratory failure and œdema of the lungs seemed to come on more quickly when pilocarpine was used than without it, and there appeared to be a causal connexion between the two. He thought the newer diuretics, containing arsenic and mercury, were scarcely safe in the treatment of uræmia. In these cases the protein should be cut down at an early stage. Sepsis was a very grave incident in precipitating metabolic disaster. His conclusion was that the only cases suitable for diaphoresis were those in which there was a good deal of œdema. More water was secreted following a hot-air bath than with any other method, and after a few days sweating occurred at a lower temperature than at first. In the absence of œdema he did not favour diaphoresis, because it put too much strain on the heart.

Dr. T. Izod Bennett expressed doubt about uræmic vomiting being a physiological or compensatory mechanism; he preferred to regard it as a toxic manifestation. The factor mainly responsible for deaths from uræmia was the dehydration following excessive vomiting. Therefore he thought life could be saved in many of these cases by stopping the vomiting—e.g., by means of barbituric acid, or even by morphia. In uræmic asthma when there was marked air-hunger, sodium bicarbonate in large doses might bring about a rapid change for the better. He agreed that venesection was valuable in these cases. In many comatose patients magnesium sulphate would restore consciousness. Much depended on the type of renal lesion. In some acute cases the restoration of consciousness started an improvement which ended in restoration to health.

Dr. Otto Leyton agreed that the amount of urea in the blood was not necessarily a measure of the uræmia, so called. Urea had to be in a state of high concentration in the blood before it caused symptoms. Many years ago it was largely the custom to give the lactic acid-forming bacillus, but that was useless unless it was properly prepared. In cases of uræmia with a good deal of œdema he had several times carried out with benefit the method advocated by the late Dr. William Ewart—namely, to sit the patient up so as to encourage the collection of fluid in his legs, and then slice the legs and liberate many pints of fluid, which was found to contain 0·1 per cent. of urea. He had known patients go five months before the fluid collected again.

Dr. A. A. Osman said that a series of patients with chronic parenchymatous nephritis of five years' standing, with considerable œdema but little evidence of nitrogen retention, were given large doses of alkalis, and in each case the œdema satisfactorily cleared up in a few weeks. It was thought that the dose of alkali could be diminished, but when an attempt was made the œdema showed signs of returning. During the period of treatment, however, the blood-urea increased. He had found lumbar puncture very useful in uræmic cases, and he had not seen harmful results. He did not favour decapsulation of the kidney, for diuresis could be increased by other means. He thought a high protein diet had a harmful effect by forming much acid; this could sometimes be counteracted by giving alkalis.

The Chairman thought that venesection was valuable but should be carried out only in the early stage. He had seen late cases in which there was only 30 to 40 per cent. of hæmoglobin, and in them venesection would be very risky. They stood more in need of transfusion, if this was thought worth while. He had seen two patients who, with a high degree of alkali in the blood, were treated surgically for other conditions, and who developed uræmia. Before giving alkalis it was necessary to be certain of the diagnosis, and to have estimates of the alkali reserve and the hydrogen-ion concentration. Vomiting was apt to increase the alkali reserve.

Dr. Arthur Phear held that pilocarpine was dangerous in these conditions, though it seemed useful in promoting sweating if the patient had a stubborn skin which did not sufficiently respond to the hot-air bath. In doses of gr. 1/10 to 1/20 it made all the difference. Lumbar puncture was valuable in a limited number of cases, including those with acute cerebral symptoms.

Sir William Willcox stressed the importance of making sure that the case being dealt with was actually uræmic. Advanced morbus cordis, impaired hepatic function, and arterio-sclerosis with changes in the cerebral vessels, might produce symptoms closely simulating those of uræmia. Prognosis was harder in renal cases than in any others. Vapour baths for uræmia were dangerous unless the heart was in good condition; he had seen a patient die from a vapour bath. Hot-air and electric baths he regarded as much safer. Eliminations by the bowel could be greatly helped by colon washing. Caffeine sodium salicylate was valuable in doses of grs. 2 every four hours in promoting the excretion of the kidney. It was a vexed question whether morphine should be given in renal cases and no definite rule could be laid down. If it was given, gr. 1/8 or 1/10 was ample. For the headaches or uræmia large doses of bromide were helpful.

Prof. Langmead briefly replied.

SECTION OF NEUROLOGY.

At a meeting of this Section held on Feb. 13th, at which Dr. Gordon Holmes, the President, took the chair, a discussion on the

Relation of Nervous Symptoms to Nervous Lesions

was opened by Dr. S. A. Kinnier Wilson. As a beginner in the study of nervous diseases, he said, it had seemed to him practical to separate cases in accordance with their particular semiology. A given disease was represented clinically by a corresponding syndrome, and even if the generic picture was specifically modified it could be relied on for purposes of diagnosis. He had soon realised, however, that the same symptom or symptom-complex could arise in association with lesions at different levels in the nervous system and as a result of different pathogenic actions. He had then, under the influence of teachers of 25 years ago, attempted to rely on the well-tried clinico-anatomical method, to correlate symptoms observed during life with lesions found after death. The method had value, for such correlation was (with certain provisos) legitimate enough and its employment had led to important discoveries and advances. Now, however, he was convinced that neither a clinical nor a pathological classification offered any particular advantage from the standpoint of nosology and that the sole basis for the scientific arrangement of nervous disease was ætiology. This was precisely the department of research which had lagged behind, and the causation of a large number of nervous affections was undiscovered. Until it was possible to prove that a given causative agent produced invariably and solely the same reaction in the body, distinct from other reactions and amenable to the same treatment, it would be impossible to establish disease entities.

Physiological Nature of Symptoms.

An ætiological factor—a pathogenic agent—could be regarded physiologically as a stimulus, and physiology recognised only three classes of stimuli: pure excitants, pure depressants, and those which first excited and then depressed. Clinical symptoms, therefore, represented either excitation or cessation of function or a series in which cessation followed excitation. All symptoms were functional in the sense of being related to function, and the attempt to distinguish functional from organic symptoms was therefore meaningless. Moreover, a symptom, being the expression of a physiological reaction, could not be specific, for the great diversity of stimuli showed that reactions themselves could not be specific. An Argyll Robertson pupil was just as characteristic of collicular neoplasm as of neurosyphilis, and he had seen every single symptom of hydrophobia manifested in a case of tetanus. Again, a symptom, being the expression of an active process, was in essence fluctuating and variable, whether it was "functional" or "organic." The tremor of paralysis agitans was as patently influenced by psychical stimuli as that of hysteria. Only when a structural change was permanent and tissue reaction had come to an end did a given symptom become "fixed." It therefore bore no constant relationship to underlying structural alterations. The conclusion was unavoidable: that symptoms were the expressions of dynamic alterations in function, and might or might not coincide with structural change; and that symptoms due to dynamic or to static change could not be differentiated.

The clinico-anatomical method was beset with pitfalls. In the first place, it was necessary to consider the precise nature of the semiological picture during life; whether the symptoms corresponded to enhanced or diminished function. Stimulation of function could not be associated with destructive lesions; they could only abolish function. "Positive" symptoms, on the other hand, could only be produced by the action of healthy mechanisms. It was illogical to attribute the involuntary flexor spasms of a case of paraplegia to lesions in the pyramidal tract; they could only occur if the lower spinal reflex arcs were sound. Jackson had said that the tabetic walked badly, not with his withered dorsal funiculi, but "with what of his spinal cord is left." The problem of all involuntary movements was physiological and would never be solved by ascribing them to destroyed cell-fibre systems. Secondly, there was no constant relationship between the size of the lesion and the amount of functional disorder. The enormous functional disturbance of a generalised major epileptic seizure bore no relation to any lesion that might be found afterwards, and many gross lesions such as cerebral tumours were unaccompanied by symptoms. Thirdly, the localisation of a symptom, a functional system, and a lesion were different and separate things; they were not comparable, could not be superimposed, and obeyed differing rules of localisation. Fourthly, the clinico-anatomical method took no account of time. The fact that the cells of the substantia nigra might be destroyed in four days in rabies and in three weeks in acute epidemic encephalitis made it very doubtful whether the parkinsonian syndrome could be attributed to their absence. A syndrome the unrolling of which involved the idea of succession in time could not be localised by spatial rules. There was no localisation of the inverted sleep-rhythm in post-encephalitis; its localisation, like that of a tune in a musical-box, was chronogenic. The mutual independence of lesions and symptoms threw light on the true nature of "disease," a term which Dr. Wilson preferred to replace by "reaction."

Even neuropathological changes were not specific; they might be classifiable, but they were nothing more than reactions to noxious agents and the features of any one were common to many others. Prof. Spielmeyer had pointed out recently [1] that the most varied injuries finally led, by a more or less long chain of causes, to the same pathophysiological process.

In conclusion, it was imperative to regard disease processes, whether of activity or depression, as indications of vital efforts to cope with noxæ; many symptoms were signs of health and many lesions were evidence of attempts at repair.

Dr. MACDONALD CRITCHLEY, Dr. P. C. CLOAKE, Dr. L. KUBIE, Dr. J. G. GREENFIELD, Dr. F. PARKES WEBER, and the PRESIDENT complimented Dr. Wilson upon indicating a point of view from which a new insight would undoubtedly be gained into many aspects of neurological disease.

Dr. E. ARNOLD CARMICHAEL then read a paper, composed by himself and Mr. J. PATERSON ROSS, entitled

RADIUM AND NERVOUS TISSUE: AN EXPERIMENTAL STUDY.

The authors had studied the effect on the brain tissue in rabbits of radon seeds buried in the dura mater and laid upon it, and of radium needles laid upon the dura mater. The results of the first series of experiments had been discarded because of the impossibility of distinguishing hæmorrhage due to trauma from that (if any) due to the radium emanations. The second series had been controlled by the application to certain rabbits of empty containers, which had caused no changes. In the brains to which active seeds had been applied there had been slight congestion of the neighbouring tissues in three hours, and the microglial cells had shown some resistance to staining. At the end of six hours the endothelial vessels had shown definite fatty changes, and difficulty had been found in staining the cells immediately below the seed. After nine hours the condition had spread deeper into the brown substance and over the surface of the cortex; there had been an extravasation of polymorphonuclear leucocytes. After 16 hours the lesion had still further extended in area and depth; the vessels were congested and leucocytic extravasation had taken place below the meninges. After 20 hours hæmorrhages were present and there was considerable swelling of the microglial cells round the edge of the lesion, which was wedge-shaped with its base on the cortex. The grey matter in the centre stained very poorly and it was possible to make out the nerve-cells only with difficulty. After 24 hours the hæmorrhage had increased and was visible macroscopically on the cortex; the neurone fibrils in the neighbourhood of the seed were unstainable and one of the myelin sheaths had disintegrated; moreover, at a distance the myelin seemed to have suffered more than any other part of the nervous system.

A series of experiments had then been carried out on the later results of the application of radon seeds of 0·3 and 0·5 mm. platinum filtration. With 0·3 mm. of filtration the size of the lesion had progressed up to 212 hours both in depth and area, hæmorrhage being observed macroscopically. The changes had progressed downwards as far as the ventricle. After 40 days the lesion had changed in character; the hæmorrhage tended to disappear and was replaced by a whitish material with a ring of congested vessels. The necrotic area became detached and the lesion tended to heal. The period of 212 hours appeared to be coincident with the projectivity of emanations from

Reviews and Notices of Books.

MOBILIZATION OF ANKYLOSED JOINTS BY ARTHROPLASTY.

By W. RUSSELL MACAUSLAND, M.D., Surgeon-in-Chief, Orthopædic Department, Carney Hospital; and ANDREW R. MACAUSLAND, M.D., Orthopædic Surgeon, Carney Hospital, Boston, Massachusetts. Philadelphia: Lea and Febiger. 1929. With 154 engravings. Pp. 252. $4.

Dr. Russell MacAusland, on whose shoulders the orthopædic mantle of Murphy seems to have fallen, shares with Dr. Willis Campbell probably the honour of being the best-known American exponent of the art of making new joints. Formerly the joints of the upper extremity when stiffened by disease attracted surgical efforts for their cure. This was because the disability resulting from a stiff elbow, wrist, or shoulder is far greater than that from a stiff knee or hip, supposing that any of the last-named joints are ankylosed in a favourable position. The knee, which depends so much for its stability upon the restraint of ligaments, long seemed an unfavourable field for arthroplasty, till Putti, of Bologna, improved upon the pioneer work of Murphy. The success of his attempts reminded us of the fact, which had nearly been lost sight of, that muscles play an even greater part in the control and support of joints than do ligaments, and that their action is capable of taking the place to a very great extent even of such a complicated arrangement as the ligaments and cartilages of the knee-joint. The differences of function of the upper limb from the lower affect the prospects of attempts to restore movement in a case of ankylosis, for a weight-bearing joint like the knee requires a much greater degree of stability than one like the shoulder, of which the weight-bearing function is quite subsidiary.

This book is divided into four parts. The first is on ankylosis, its causes and treatment, including a useful discussion of what the authors call the *functional* position of various joints, by which is meant that position which allows of the most extensive performance of the functions of the limb, despite the stiff joint. The second part is on arthroplasty in general. The writers here maintain that an arthroplasty is not an excision, but something quite different. The point is not very important; we ourselves hold that an arthoplasty is an excision, but one specially modified for the special purposes of procuring movement with stability. The historical portion of this part is of much interest and value. The authors give full credit to other operators, and the work of previous and contemporary surgeons receives due notice. Under the heading indications and contra-indications much valuable advice, the fruit of a wide experience, is offered to the reader. Part III. deals with the arthroplasty of specific joints; here eight joints are discussed, but the authors lay it down elsewhere as a categorical rule that there are practically only five joints in which mobilisation is justified—namely, the temporomaxillary, the elbow, the knee, the hip, and the first metatarsophalangeal joint. As regards this last, we believe that those surgeons are right who hold that a free excision of the head of the metatarsal bone gives the best obtainable result, and we would thus reduce the number of joints suitable for arthroplasty to four. The authors hold that "in only very rare instances are the shoulder and the wrist subjects for mobilisation, and under no circumstances is arthroplasty to be considered in the ankle-joint." Part IV. is devoted to a consideration of the prevention or minimisation of ankylosis. Operators in general, including the authors, Putti, Willis Campbell, and others, nowadays use free flaps of fascia in arthroplasty. The old theory of Murphy that the flap needed an isthmus connected with its site of origin for its nutriment has been proved to be fallacious. There is still room for some doubt as to what becomes of fascial flaps in successful arthropathies. The balance of evidence inclines to the theory, supported by the authors, that the fascia is transformed into a connective tissue which acts as a covering for one of the articular surfaces.

This valuable monograph is well illustrated, and the various operative procedures are fully described.

HEREDITY AND PARENTHOOD.

By S. C. SCHMUCKER, Ph.D., Sc.D. London: Macmillan and Co., Ltd. 1929. Pp. 322. With 42 figures. 10*s.* 6*d.*

THERE are perhaps quite enough books nowadays on heredity, sex, and sex relationships. But there is still room, we think, for one written in the admirable temper of Prof. Schmucker. He gives, professedly for those with little or no biological knowledge, a straightforward, easy account of inheritance and sex. It does not everywhere reach a very high standard of accuracy in detail; the bursting of a boil, for example, is not achieved by just the mechanism which he describes on p. 144. But he tells his tale with singular clearness, and the whole is imbued with a dignity, restraint, and simple human kindliness which is particularly welcome in these times.

ÉTUDES NEUROLOGIQUES.

Troisième série. By GEORGES GUILLAIN, Professor of Diseases of the Nervous System in the Faculty of Medicine of Paris; Physician to the Salpêtrière. Paris: Masson et Cie. 1929. Pp. 453. Fr.70.

WE have had occasion to review from time to time the volumes of neurological contributions made by the present holder of the Charcot chair in the Paris faculty, who is a worthy successor to Raymond, Dejerine, and Pierre Marie. Prof. Guillain again places the neurologist in his debt by a further series, embracing papers of outstanding interest, most of which have appeared during the last few years. Three are devoted to infection with cysticercus, a condition seldom seen in this country but well known from the work of mid-European investigators. A somewhat provocative and controversial paper deals with the apparent occurrence of Jacksonian epilepsy in association with lesions of extracortical site. While this does not constitute a clinical novelty, it must require careful and critical consideration. Absence of macroscopical change at operation cannot of itself invalidate the usual conceptions of Rolandic localisation, and the instances here brought forward by Prof. Guillain seem to have belonged mainly to a vascular class. In none of them do we think it absolutely proved that the motor cortex was not physiologically influenced in direct fashion by lesions in its vicinity. A readable contribution discusses the comparatively rare syndrome of Foville, which Prof. Guillain shows may occur simultaneously on the two sides. Polyneuritis cranialis is another topic of interest, a descriptive account being furnished of the syndromes associated with lesions at various foramina of the skull and in other spots where cranial nerves are in apposition. The clinico-anatomical method, traditional in the French school, is here seen at its best; while the charming style of the writer and the lucidity of his language enable us almost to imagine we are sitting in his clinic, and must surely attract all students and practitioners of neurology.

VACCINE THERAPY.

Immunisation locale contre la tuberculose par voie cutanée. By J. DEKKER. Amsterdam: H. J. Paris. Pp. 108 and plates. 7s. 6d.

THIS book, which has a foreword by Prof. Besredka, consists almost entirely of a record of cases treated by the author's special method of vaccination. The vaccine is administered by placing 6 drops of vaccine on to two skin scarifications of 8 cm. length, after a preliminary test scarification of 1 cm. length. Vaccine A consists of a mixture of tuberculin and an emulsion of dead tubercle bacilli. Vaccine B has in addition staphylococcus, streptococcus, pneumococcus and the influenza bacillus. One hundred cases are recorded. The history of the patient, together with the symptoms, is given in all cases, but the physical signs are only briefly enumerated, and very few laboratory tests, such as the finding of tubercle bacilli in sputum or other excretions, appear to have been used to clinch the diagnosis. Radiograms were taken in a considerable number of cases; a small collection of radiograms of pulmonary cases before and after treatment is given, also photographs of one lupus case before and after treatment. The work does not appear to be very well documented, and it is difficult to arrive at a satisfactory assessment of the value of the method of treatment from a mere perusal of the book. The author is himself evidently fully convinced.

LIPPINCOTT'S POCKET FORMULARY.

Second edition. By GEORGE E. REHBERGER, M.D. London: J. B. Lippincott Company. 15*s*.

THIS book, of suitable size for a capacious pocket, though hardly what one would like to carry constantly, is a satisfactory sample of the literature on which the practitioner should consult when faced with the treatment of some disease with which he is not familiar, or of one on which he has exhausted his usual remedies. In the first half diseases are given in alphabetical order with a plentiful list of prescriptions and suggestions. The author himself seems to be in doubt whether they are not too numerous, but the essential thing in such a compilation is completeness. The second half of the book is divided into three parts, containing respectively the drugs given in the U.S.P. (tenth edition). National Formulary, and the New and Non-Official Remedies. It is a useful book brought well up to date in this edition.

Reports and Analytical Records.

THE GERMICIDAL ACTION OF DIMOL INTESTINAL ANTISEPTIC.

(MANUFACTURED BY THE DIMOL LABORATORIES, LTD., 40, LUDGATE-HILL, LONDON, E.C.4. DISTRIBUTED BY MESSRS. SANGERS, LTD., 258, EUSTON-ROAD, N.W.1.)

WE have been asked by Captain Ainslie-Walker, of the Dimol laboratories, the originator of Dimol Intestinal Antiseptic, to examine the germicidal action of the antiseptic in any manner which might suggest itself to us and to report our findings to the medical profession. An independent bacteriologist was asked to carry out these tests, and he has reported as follows:—

It is manifestly useless to endeavour to conduct experiments in such a manner that *in vivo* conditions are simulated. It was thought, therefore, more satisfactory to deal with *in vitro* tests.

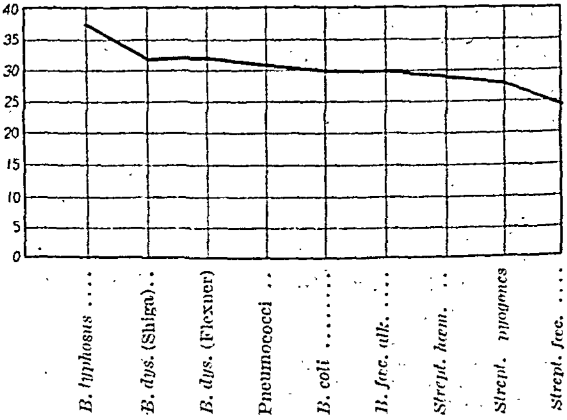
Dimol antiseptic is a granular powder of brown colour having a heavy, phenolic odour. It is sparingly soluble in cold water, but if treated correctly yields a very fine emulsion. This is highly satisfactory since it is well recognised that, from the germicidal point of view, a good emulsion acts more efficiently than a true solution. The makers recommend that the powder be rubbed up with a little cold water into a smooth paste and then diluted with water at 70° C., the emulsion being kept in a water-bath at this latter temperature for a few minutes.

Prepared in a proper manner it was found possible to obtain an emulsion which actually gave a higher Rideal-Walker coefficient, using *B. typhosus* as the test organism and carbolic acid as a standard, than is claimed by the inventor of the preparation; with such a good emulsion a figure of 37 was obtained compared with the factor 35 claimed. The method of preparation of the emulsion affected very considerably the result obtained in Rideal-Walker tests, and it is important that the directions of the manufacturers should be followed closely. Good emulsions then remain perfect for more than two weeks.

1. *Determination of the Rideal-Walker coefficient of Dimol using organisms isolated from the fæces.*—For these experiments typical strains of the organisms tested were isolated from fæces examined in the laboratories of a large general hospital. The Rideal-Walker technique was followed closely; any variations lay chiefly in the direction of media suited to the growth of the organisms under test; 0·5 c.cm. of the test culture was used as inoculum in the medication tubes. The values so obtained were as follows:—

Test organism.	Rideal-Walker coefficient.
B. typhosus	37
B. dysenteriæ (Shiga)	34
B. dysenteriæ (Flexner)	34
Streptococcus fæcalis	24
,, *pyogenes*	27
,, *hæmolyticus*	28
Pneumococci	32
B. fæcalis alkaligenes	30
B. coli	30

When viewed in the form of a graph the coefficient show a remarkably level line, only dipping slightly in the case of *Streptococcus fæcalis*, an organism most probably of little clinical importance.



2. *Determination of the degree of dilution of the antiseptic leading to death of the organisms in 15 minutes.*—These tests gave the following figures:—

B. typhosus	1:6500
B. dysenteriæ (Shiga)	1:6250
B. dysenteriæ (Flexner)	1:6000
Streptococcus fæcalis	1:5500
,, *pyogenes*	1:6000
,, *hæmolyticus*	1:6000
Pneumococci	1:7000
B. fæcalis alkaligenes	1:6000
B. coli	1:5000

These figures are interesting as showing that, with a longer time factor, all the organisms closely resemble one another. All the tests were carried out at body temperature, 37° C.

3. *Examinations for toxicity.*—Some difficulty was met with in feeding experiments with animals. Single doses up to 0·02 g. (equivalent to 1/3 gr.) per kilogramme body-weight were given to rabbits without producing toxic effects. Such a dose corresponds to grs. 20 for a man weighing 10 stone, five times the dose advocated for therapy. No evidence of absorption as shown by carboluria was obtained. Repeated doses equivalent to two and a half times those recommended in therapy also failed to produce ill-effects when given three times daily over a period of four weeks.

Conclusions.—(1) Dimol intestinal antiseptic is found to possess a very high Rideal-Walker coefficient against the commoner organisms infecting the intestine. (2) The antiseptic kills completely these organisms in 15 minutes in dilutions ranging to 1 in 7000. (3) The preparation shows no evidence of producing toxic effects in animals even when given in very large doses. No carboluria was produced.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 22, 1930.

SURGICAL ACCESS TO THE CHEST.

UNTIL fairly recently the chest was regarded as out of bounds to the surgeon because it was thought that, apart from such operations as those required for acute and chronic empyema, any surgical interference would almost certainly result in rapidly fatal spontaneous pneumothorax. Nowadays, the thoracic surgeon is widening his field of activity, and operations which were undreamt of at the beginning of the century—such as the removal of tumours of the lungs, pleura, and mediastinum, and the draining of deep-seated pulmonary abscesses—are becoming commonplace. Lobectomy and even pneumectomy have been attempted, although the immediate operative mortality has not been reassuring.

The very real advance in thoracic surgery can be estimated by studying and contrasting the surgical text-books of the early part of the present century with those of the present day. The progress made is indeed striking. The reasons underlying this rapid increase in knowledge and interest in pulmonary disease are many. Among the most important is the development of radiology with its concomitant use of lipiodol for the purposes of diagnosis. Improved bacteriological and chemical methods have contributed largely to better diagnosis. The general adoption of artificial pneumothorax in the treatment of pulmonary tuberculosis and allied conditions has not only been of great value from the therapeutic standpoint, but has also been of assistance to the radiologist in his diagnosis of such conditions as new growths of the lung, and benign tumours of the mediastinum. The surgeon has been able to attack more easily such conditions as growths of the thoracic portion of the œsophagus and mediastinal tumours, when the lung has been previously collapsed artificially. Much has been learnt also of the mechanics of respiration and gaseous exchanges. Amongst other things it has been shown that a patient can have a considerable degree of collapse of both lungs with no appreciable embarrassment of the respiratory or cardiac functions. All these factors have led to an increased clinical interest—as, for example, in the correlation of physical signs with radiological appearances—and also to an added interest in the study of physical signs for their own sake. But it was the late war which afforded the greatest stimulus to the study of chest surgery, for it yielded a concentrated mass of clinical cases with wounds of the chest of every description, and brought forth a new conception of the physics of the lungs and pleural cavities. Such conditions as massive collapse of the lung following injury, and surgical infections of the lungs and pleura were studied in great detail. It was seen quite early in the war that a soldier with an open pneumothorax did not necessarily die immediately, and that, on the contrary, many such cases recovered completely. The modern view arising out of war experience of the mechanics of open pneumothorax is that if an opening in the pleura is of smaller extent than the aperture of the glottis, the lung collapses gradually, and the intrapleural pressure remains negative. This type of pneumothorax does not cause respiratory embarrassment. If, however, the communication through the pleura with the outside air is larger than the aperture of the glottis, the lung collapses suddenly, and the mediastinal contents are displaced to the opposite side by the negative pressure set up by inspiration. On expiration, when the pressure becomes positive, the mediastinum returns to its original position, and in this way a to-and-fro flapping movement is produced, leading to disturbance of cardiac and respiratory function and characterised by cyanosis, dyspnœa, and irregular action of the heart. Before the war efforts had been made to prevent the possibility of fatal pneumothorax in operations on the chest, notably by SAUERBRUCH with his negative pressure operating chamber (hypo-atmospheric method) and by MELTZER, who introduced the intratracheal insufflation method by which the anæsthetic, mixed with air or oxygen, is pumped above atmospheric pressure through a catheter in the trachea into the lungs (hyper-atmospheric method). In this country only the latter method, or modifications of it, are now used.

During the past ten days in London a great deal of discussion[1] on respiratory diseases has been taking place. At the Royal College of Surgeons, the President of the Royal College of Physicians delivered a Hunterian Lecture on Massive Collapse of the Lung. The Section of Surgery of the Royal Society of Medicine discussed the question of Intrathoracic Tumours, while the Section of Anæsthetics, in conjunction with surgeons, held a discussion on Anæsthesia in Thoracic Surgery. The Medical Society of London dealt with the surgical methods of collapse of the lung, accessory or alternative to artificial pneumothorax, and Dr. GUSTAV MAURER, of Davos, read a paper on the Surgical Treatment of Pulmonary Tuberculosis, in which he referred mainly to the nature of adhesions in artificial pneumothorax and his "two puncture" method of dividing them. The value of cutting adhesions in artificial pneumothorax in order to obtain complete collapse of the lung is a matter on which opinions are divided. Frequent endogenous infection of the pleural cavity leading to empyema and tuberculous exudate brought the method, first instituted by JACOBÆUS, into some degree of disrepute. It is doubtful whether adhesions in the majority of pneumothorax cavities prevent a good functional result. The basic idea underlying collapse therapy is not, as might be supposed, to rest the lung completely, but in order, as STUART TIDEY[2] has pointed out, to release the edges of the ulcerated area from the tension of the surrounding lung tissue, and thus to promote healing. It has been shown by UDAONDE and VADONE[3] that a completely collapsed lung is never at rest. In some cases the presence of adhesions prevents a good functional result. The figure of 37 per cent. given by GRAVESEN and the MATSONS is, of course, purely arbitrary, as it depends on the type of case selected for the treatment. MAURER, in his classification of adhesions found in these cases, shows that, in the majority, devitalised lung tissue is caught up in the adhesion, which if divided through the tissue of the lung allows endogenous organisms to infect the pleural cavity. From this fact he makes the interesting point that in order to prevent endogenous infection, the adhesion must be divided as close to the parietal pleura as possible. MAURER'S method should give the best results in those cases in which adhesions prevent the collapse of pulmonary cavities, but unfortunately in many of those cases a type of adhesion exists which finds no place in his classification—viz., those in which the lung is firmly adherent over a wide area to the parietal pleura with no demarcation between the pleura and the lung tissue. It is these cases in which an attempt to divide the adhesion would be most dangerous. The difficulties which adhesions set up in artificial pneumothorax seem to suggest that the best time to institute the treatment is at the earliest possible moment, without trying more conservative methods of treatment and allowing adhesions to form. It is true, however, that often by the time that the patient consults his doctor adhesion between the pleural layers has already taken place.

[2] Compression of Lung in the Treatment of Pulmonary Lesions (London, 1927).

[3] Arch. méd.-chir. de l'appar. resp., 1928, iii., 363. See also THE LANCET, 1929, i., 621.

It is a curious fact that artificial pneumothorax, a minor surgical operation, is considered in this country and elsewhere to come within the province of the physician. But it is really an indication of the fact that for the successful diagnosis and treatment of pulmonary disease, a team of skilled workers, consisting of physician, surgeon, radiologist, laryngologist, anæsthetist, and bacteriologist is necessary. On the Continent there has appeared the chest specialist who is a physician-surgeon-radiologist, and in isolated instances in this country the same combination is to be observed. The success of a team depends on the individual members of it, and under Utopian conditions, no doubt, would be of greater efficiency than the man who might be somewhat irreverently termed the Pooh Bah chest specialist. But there seems to be no reason why the man who has specialised thoroughly in chest diseases should not be able to combine both medicine and surgery and perhaps radiology of the respiratory system.

◆

SLUM CLEARANCE AND THE RATING SYSTEM.

On Wednesday in last week a resolution was moved in the House of Commons which asked the House to regret the excessive burdens placed on the occupiers of new houses by the present rating system, as well as by street-paving charges, while the detrimental effect of these burdens upon future housing activities was clearly pointed out by the participants in the debate. The object of the resolution was to urge the Government to consider proposals for some scheme of adjustment or modification of rates, when the question of housing came up for future legislation, an event that is due to occur promptly. For in the King's Speech at the opening of Parliament the promise was made that an extensive programme of slum clearance would be promoted, and, of course, the clearance of the slums means the construction of accommodation for the dislodged inhabitants.

It is an unfortunate fact that until now the rents, with the accompanying rates, demanded for any new houses, are usually—it might almost be said invariably—in excess both of what any previous slum-dweller has paid or what he can pay. This is not to say that there is any systematic extortion about the rent charges, for their scale can be shown to depend mainly on the cost of land and building. But the rates and other charges are dictated by the rent, and the total cost to the tenant is such that those who should benefit by slum clearance are unable to do so. The resolution before the House was moved by Mr. Philip Oliver, who suggested a way out of this dilemma through a system of differential rating, with a communal charge for any cost of street-making which could not be regarded as due to the requirements of the residents of that street. Mr. E. D. Simon, in seconding the resolution, appealed to the Minister of Health to deal bravely, in connexion with the forthcoming Housing Bill, with the present system of rating, which he described as faulty and antiquated. But an intervention from Sir Kingsley Wood here raised the important point that to deal with the question of rating in a Housing Bill, according to the lines proposed by the supporters of the resolution, would unduly burden a large number of working men and women who were already making a fair contribution as taxpayers to the State support of housing development. To some extent the Minister of Health was in agreement here, for he pointed out that the gist of the resolution was to obtain a further subsidy from the State, whether by means of derating or by reducing the road-making charges or both, while at the present moment the State was already contributing something like one-third of the cost of the publicly assisted houses now under construction. Mr. Greenwood did not defend the system of rating—indeed, he condemned it in general terms, but he said that he could not see the justice of derating the persons who happened to be fortunate enough to live in new houses at the expense of those who lived in the old houses. It is clear that the problem of rating will not be dealt with in connexion with the new housing scheme.

The probability is that the movers and supporters of the resolution, which was agreed to by the House, did not anticipate that the many social problems which will naturally come up for discussion under the Housing Bill would be added to by including rating questions in the measure. But it is to be hoped that Mr. Greenwood, as an important member of the Government, will see that the representations on the subject will not be forgotten, and will make their appeal in some more appropriate manner. The housing shortage is being met; the absolute dearth is being replenished, more satisfactorily in some areas than in others, and we may expect that the results will be expressed to some extent in vital statistics. This should encourage the Government to think comprehensively in their contemplated measure, recognising that the housing difficulty continues to be an effective obstacle to the promotion of public health.

THE TREATMENT OF URÆMIA.

Of the more immediate causes of death which occupy the attention of the practitioner, uræmia is one of the most frequent and striking, and the informal discussion on its treatment which took place at the Royal Society of Medicine last week is of importance to all branches of medical practice. A full report of this discussion, in which several sections of the Society took part, appears in other columns of our present issue. The term uræmia is admittedly inexact and covers a very large number of phenomena, but there is general agreement that serious failure of renal function is an essential part of any syndrome which may properly be included in this term. The main groups of symptoms to which this name is applied are familiar enough, whether it be the group with convulsions and amaurosis, with renal asthma or marked respiratory manifestations, or with prominent cerebral and gastro-intestinal symptoms. Intensive study should, in course of time, tend to increase our knowledge sufficiently to enable us to define with some exactitude the changes in the chemistry of the body fluids which underlie these varying syndromes. Possibly this increased knowledge may enable the expert of the future to separate the group of definitely irrecoverable cases from others in which it is possible with some certainty to institute effective therapy. Although, as Prof. F. G. LANGMEAD pointed out in opening the discussion, uræmia is only too often a late symptom of an incurable disease, it does sometimes manifest itself to us as an acute disturbance threatening life in a patient in whom the renal damage is not, in itself, incurable. Cases of acute nephritis in children are sometimes attended with uræmia, the treatment of which has been followed by a large and sometimes permanent measure of repair to the nephritis and consequent restoration to perfect health. Urologists, again, are acquainted with the alarming manifestations of acute renal failure which sometimes follow stages in the operative treatment of prostatic obstruction, and they have seen such patients enjoy good health for years afterwards if the menace of the immediate attack can be held off. It would, therefore, seem that in uræmia it is important for the practitioner to form a sound estimate of the amount of permanent damage present in the kidneys of a patient he is treating; if he is able to satisfy himself that this damage is not irreparable it becomes of urgent importance for him to adopt the proper measures for counteracting the acute crisis which is superimposed.

A cloud of uncertainty still hides from us the exact interpretation of uræmic symptoms, although it may be stated with little risk of contradiction that twitchings and convulsions are evidences of disturbed calcium metabolism, that uræmic asthma and air-hunger are usually an indication of a lowering of the alkali reserve of the blood, and that uræmic coma is, at least in many instances, an expression of increased intracerebral tension. In the discussion already mentioned, Dr. IZOD BENNETT expressed the opinion that vomiting, which is often so prominent a feature in surgical cases, is not infrequently the cause of death owing to the progressive dehydration of the patient. He had, he said, seen life saved on many occasions by the energetic exhibition of drugs, such as the barbituric acid compounds, or even morphia, which would prevent vomiting of this type. Dr. E. P. POULTON, Dr. LANGDON BROWN, and several other speakers emphasised the importance of diet in uræmia, whether threatened or actually present. While it is true that nitrogen retention may be present for years without the production of uræmia, and equally true that the most rigorous diet, with reduction of proteins to a bare minimum, is powerless to prevent nitrogen retention once this has occurred, there was general agreement that anything approaching a moderate protein diet, let alone a high one, might rapidly be followed by disaster. A possible alternative explanation of this was advanced by Dr. A. OSMAN, who instanced the acid-producing tendency of protein diets, a subject on which we must look to the future to supply exact knowledge; it is, however, already clear that a diet which tends to keep the reaction of the blood close to its physiological normal level without effort on the part of the kidney is clearly desirable in all cases where its function is impaired. Many speakers of experience who contributed to the discussion emphasised the need to promote excretion by purgation, by sweating, and possibly by venesection, but they were careful to qualify their statements by an admission of the frequent inefficacy of such measures when applied alone. Coöperation with the biochemist will long be required before the physician can regard the therapy of uræmia with satisfaction.

Annotations.

"Ne quid nimis."

ANOTHER SCOTTISH MILK EXPERIMENT.

THE usefulness of adding milk to the diet of elementary school-children was demonstrated two years ago by an experiment in Scotland.[1] This experiment was instructive and convincing, but it was confined almost entirely to town schools and its basis was somewhat narrow. After much consideration, the Secretary of State for Scotland has therefore decided in favour of a further investigation, and this was inaugurated at Hamilton last Saturday by Mr. Tom Johnston, Parliamentary Under Secretary of State. It will involve 20,000 school-children from 100 schools in the County of Lanark. From Feb. 17th until the schools close in July, some 10,000 to 12,000 children will receive an additional forenoon ration of three-quarters of a pint of milk. Five thousand of these children will receive Grade A (" tuberculin-tested ") milk; another 5000 will receive pasteurised milk, while 10,000 " controls " will be weighed and measured but will get no added ration. Over 9000 gallons of milk will be supplied daily through the Milk Pool (Scottish Milk Agency, Ltd.) and the cost of the experiment is expected to be about £9000. Of this sum the Empire Marketing Board are to contribute £5000 and the Central Advisory Committee of the Miners' Distress Fund £2000. The investigation will serve several purposes. It will constitute a more searching test of the value of milk as a food for growing children. It will increase the consumption of milk in Scotland, which is in this respect behind many other countries. It will considerably help the milk-producing trade, and it will also do something to inform the general public of the value of standardised milk. Incidentally, it will afford relief in the depressed mining areas. The previous experiments, conducted over two years, showed some of the possible mistakes in research on a large scale, and those in charge of the present investigation will benefit by the experience which has been gained.

THE HICKMAN MEMORIAL.

AN appeal which was launched about a year ago to recognise and perpetuate the memory of Henry Hill Hickman, a pioneer in general anæsthesia by inhalation, has been repeatedly endorsed in our own columns.[illegible] Thanks to a generous response from individuals and societies the Committee, of which Dr. W. J. McCardie and Dr. Cecil Hughes are hon. secretaries, has been able to make the following arrangements. A memorial tablet, designed and executed by Mr. Eric Gill, will be unveiled in Bromfield Parish Church, near [illegible], on April 5th next, being the centenary anniversary of Hickman's burial. His grave in the churchyard will be restored and the tombstone re-lettered. A memorial medal with an endowment fund will be awarded for original work in [illegible] anæsthesia. In addition, it is hoped to [illegible]

portrait of Hickman to be pre
Society of Medicine. Finally,
has made a valuable collect
connected with Hickman, which
at a meeting which has been [illegible]
April 2nd, the anniversary of [illegible]
understand from Dr. Hughes [illegible]
subscribers to the fund and [illegible]
will shortly be published [illegible]
Before doing so the Committee [illegible]
have overlooked the matter, and [illegible]
is due to the discovery of [illegible]

MATERNAL MORTALITY IN AUSTRALIA.

THE number of maternal deaths which occur in connexion with every thousand live births in Australia shows a steady rise since 1922, having remained more or less stationary during the previous ten years. The maternal death-rate in 1928 was 5·98, the highest yet recorded, and the Commonwealth of Australia invited Dame Janet Campbell, senior medical officer for maternity and child welfare at the Ministry of Health, to visit each of the States and to advise what measures should be tried to cope with the distressing situation. Dame Janet has now returned and her report, of which the substance was communicated verbally on Tuesday to a group of interested people, has been issued as a white paper.[1] In it she deals comprehensively with the local problem, reviewing existing facilities for maternal and child welfare and making pertinent suggestions for future action. The steady reduction of the infantile mortality of Australia from 96 per 1000 births at the beginning of this century to 52 in 1928 is an achievement to which she accords due praise. The neonatal death-rate (deaths under one month) is, however, less encouraging, and a table of death-rates of infants under one week shows that this rate is actually higher now in Australia as a whole and in all the States except Western Australia than it was 20 years ago. The significance of these deaths within a few days of birth is their association with obstetric and developmental, rather than with pædiatric causes, and it is through care of the parturient mother that improvement in the infantile mortality will be obtained. Though certain hospitals in Australia (for example, the Queen Victoria Memorial Hospital in Melbourne) have a well-organised prenatal department, prenatal work has scarcely developed at all in connexion with the fairly numerous infant welfare centres. Dame Janet Campbell's suggestions for further action include the provision of improved professional education in midwifery and antenatal and infant hygiene, since much advance will have to be made before all doctors practising in Australia are willing and competent to undertake the regular supervision of pregnant women. The expansion of the place occupied by midwifery in the medical curriculum offers more hope than the organisation of post-graduate instruction in such a large continent, where isolated practitioners may find it difficult to take advantage of any facilities provided in the great towns. As to the midwives, though the regulations for their training are similar in the different States, the practice varies considerably and the laxity of administration in certain schools requires attention.

Dame Janet condemns small training schools, where the lecture or coaching is merely an incident in the work of a busy practitioner or matron and gives cogent reasons why maternity hospitals for private patients only should not be recognised as training schools. It would be better in the long run, she holds, to train a smaller number of midwives than to allow certification after instruction which falls far below the accepted minimum requirements. In connexion with training in mothercraft, emphasis is laid on the desirability which would hardly be questioned in this country of leaving to the discretion of those responsible in each recognised institution for mothercraft the question of modifying or varying the details of instruction. "Diversity of medical opinion and practice in regard to infant feeding in Australia and elsewhere indicates that there can be no sterotyped or standard method applicable to every infant under all circumstances and suggests that the ordinary baby is tolerant of, and can even thrive upon, comparatively widely different dietaries." The administrative changes advised concern mainly the need for revision on uniform lines of the returns required on death certificates, the desirability of registration of still-births, of compulsory notification of births to the authorities concerned with infant welfare (not yet in force in all parts of Australia), and of puerperal fever.

The establishment of a maternity service whereby any woman can obtain facilities for the satisfactory conduct of a normal or a difficult confinement and the development of infant and child welfare services "under medical supervision" are also recommended. In the absence of a completely organised public health service under local authorities, Dame Janet advises: (*a*) the establishment in each State of a Division of maternity and child welfare, in charge of a whole-time medical director responsible to the chief medical officer of health; this Division might design a general and comprehensive scheme of action which should not necessarily be applicable at once in its entirety. Propaganda publicity should be encouraged and the coöperation of women's organisations enlisted. The other major recommendations made are: (*b*) the granting of subsidies, properly conditioned and adequately supervised, towards the extension and improvement of the work for maternal, infant, and child hygiene; and (*c*) the encouragement and subsidising of research into various aspects of such activities.

TETRACHLORETHYLENE AND HOOKWORMS.

IT is at last becoming possible to form a fairly sound opinion of the value for a hookworm campaign of tetrachlorethylene, the anthelmintic introduced by Maurice C. Hall and J. E. Shillinger [1] about five years ago. P. D. Lamson and his colleagues [2] have studied its anatomical and physiological effects on animals. The hepatic necrosis, so pronounced after administration of carbon tetrachloride (CCl_4), is quite absent in dogs after tetrachlorethylene (C_2Cl_4). This is so even when the stomach has been filled up by the drug, when it has been given in doses of 2 c.cm. per kg. every second or third day for several months, or when the dog has been kept anæsthetised by its inhalation for several hours. Fatty change had previously been noted in the liver, but Lamson's report suggests that it is no greater in these drugged dogs than in ordinary animals. The kidneys were unaltered in structure, nor could changes be detected in hepatic function. The experiments show further that normally the drug does not pass the dog's liver, and that this organ disposes of it without evident damage to itself. If, however, the dog be fed with fat symptoms of absorption appear; and such symptoms are indeed the rule, apart from diet, in puppies, and to an even greater degree in certain other animals. Clearly the experimental evidence cannot exclude the suggestion that absorption may take place in man.

From the clinical side P. A. Maplestone and A. K. Mukerji [3] have studied tetrachlorethylene at the Carmichael Hospital, Calcutta. Giddiness, vomiting, or drowsiness occurred in 8 of 38 hospital cases receiving 3 c.cm. of the drug. When it was combined with 1 c.cm. of oil of chenopodium these toxic symptoms appeared in 26 of 37 cases. The drugs were given in capsules, so it must be assumed that absorption occurred from the alimentary canal and that the drug passed through the liver; clinical evidence upholds the caution that the effects on the full-grown dog cannot be held fully evidential for man. These writers also investigated the worth of tetrachlorethylene against hookworms, using more exact diagnostic methods than had hitherto been employed. Counting by Stoll's caustic soda method the number of hookworm eggs passed before and after the treatment mentioned, the relative figures led to the conclusion that 60 per cent. of the worms had survived. By Clayton Lane's direct centrifugal floatation (D.C.F.) they obtained the added information that 80 per cent. of their patients remained infected, and they cite one series of 12 cases in 8 of whom Stoll's technique discovered no eggs after treatment, whereas D.C.F. showed that actually 11 of them remained infected. It is pointed out that no other investigation on this drug has employed methods exact enough to determine the extent to which it really disinfects, and the following is added: "The great superiority of Lane's method over any other for demonstrating light infections is quite sufficient to explain the low percentage of cures in the writers' cases. It was the discovery of the ridiculously low rate of complete cure that even the most powerful vermifuges bring about when checked by the direct centrifugal floatation method that led the writers to make use of the percentage reduction in eggs as a test of drug efficiency." Accurate egg-counting methods, and Stoll's is not among the most accurate, certainly give the measure of any drug's anthelmintic efficiency and form a valuable guide to the physician. They are probably of much less interest to his patient who rightly demands his own complete disinfestation; and the more clearly it is realised by both physician and patient how constantly the most popular anthelmintics fail to effect this, the more urgent will be the pressure for sustained research aiming at discovering something better. It is self-satisfying to focus attention, as is generally done at present, on a lessened egg count rather than on a gross failure to disinfest. It is more straightforward to face the fact that we have at present no sure and safe anthelmintic against hookworms.

PROSTITUTION IN NEW YORK.

THE history of the New York system of prostitution is interesting. Up to 1915 the solicitation laws there were similar in effect to those now in force in London but in that year a change was made, so that solicitation for prostitution became an offence in itself, without reference to "annoyance." In New York it is now a legal offence to "commit" or "offer to commit *prostitution*," or to "*induce, entice or procure another*" to commit fornication. In 1921 a man was arrested for breach of this law, but the magistrate held that prostitution was a practice of women only, and that a man cannot be a principal under that charge. Thus only women are now liable for that offence. The January number of the *Shield*, the journal of the Association for Moral and Social Hygiene, which takes note of this position, delineates, mostly by quotation from the official American Report, the results, up to the end of 1928, of the activities of the "Committee of Fourteen," a body which was created some twenty years ago with the object of "cleaning up" New York. The report of this Committee is mainly an exposition of the working of the present system, for which that Committee is chiefly responsible; the report therefore has no hostile bias. By constant suppression of solicitation the Committee have succeeded to a wonderful extent in "cleaning" the streets. So far so good. But the Committee are now faced with a "new and unforeseen thing." A few short quotations chosen from a long series will explain what that is.

> "There has sprung up a mushroom growth of night-clubs and speakeasies. . . which have furnished commercialised prostitution with a long-wanted place and opportunity. . . These provide at the present time the greatest source for the making of new prostitutes . . . Clandestine clubs are steadily permeating every section of the city . . . the name 'clubs' is really a subterfuge . . . Respectable and legitimate clubs have hostesses . . . the speakeasy houses of prostitution now call their inmates hostesses . . . 60 per cent. of the agencies investigated may be said to be shady, and 40 per cent. are definitely engaged in the traffic . . . One of the requirements specified by proprietors of clubs and speakeasies seeking hostesses is that they must be 'regular' . . . Instead of a white-slave traffic, the traffic is what might be termed a traffic in hostesses . . . The interchange of girls in the clubs is rapid . . . It would seem that the low-class clubs and speakeasies are virtually prostitution mills. . . Those hostesses are most valuable . . . if they will become what is called 'reasonable.' . . . Perhaps one of the most important factors is . . . the taxicab drivers, runners and doormen, who secure a percentage for introducing male guests . . . The demand (for girls) is so great that there are not nearly enough ready-made-prostitutes to supply it; hence the recruiting through employment agencies . . . There is a definite tie-up between clubs and call-flats . . . "

Commenting on the activities of the New York Committee, the *Shield* remarks that they set about cleaning up the streets before public opinion was improved, and thus prostitution has been driven underground. Not but that the police are in full cry; the number of women dealt with under charges of prostitution increases yearly; 1928 far exceeds the record of previous years. The result for the woman depends on whether she be suffering or not from venereal disease; if it is a first conviction, and she is diseased, she goes to the Avenue Hospital for an indeterminate period till she is considered no longer dangerous; for a subsequent conviction, the penalty is 100 days, or an indefinite commitment to a reformatory. Severe as these punishments are, the evil grows steadily. The Committee of Fourteen suggest as their desiderata: prohibition of all employment of females in restaurants, including those employed as singers or performers; increased allowances for police investigators; abolition of "closed" dance halls, and closer supervision of dance palaces. The fact is that the Americans have decided to move steadily along the line of suppressing prostitution; of clearing prostitutes off the streets, and subjecting them (not their male partners) to severe penalties. The report indicates that the evil is progressing under very disturbing forms. It is not the first time in history that suppression has been vigorously tried, nor the first time (if it prove so) that it has failed. Whatever view we take of it, this report, or at least the *Shield* account of it, ought to be in the hands of all who take a practical interest in the likely revision of our own solicitation laws. In this country the Street Offences Committee have published their report; a lot will depend on how far and in what manner its recommendations are given the force of law. It may be desirable to clean the streets, but it is far more desirable to clean *public opinion*.

EYE DISEASES IN CHINA.

AMONG the earliest practitioners to place Western medicine upon a sound footing in China were two very able ophthalmic surgeons, Dr. T. R. Colledge, of the British East India Company, and Dr. Peter Parker, an American missionary. Both of them founded eye hospitals in Canton and elsewhere, and Dr. Parker, between 1834 and 1844, performed numerous operations for cataract which keep alive his memory to this day as one who restored sight to the blind. The tradition thus started has continued down to our own time. The Peiping (Pekin) Union Medical College, founded in 1921, has established a department of ophthalmology which has brought in succession the renowned Ernst Fuchs, his son Adalbert Fuchs, and now Prof. Arnold Pillat, to develop its activities. The object is not so much to train ophthalmic specialists as, in view of the important rôle played by eye diseases in China, to make the native doctors more capable of dealing with the eye cases they are certain to meet in large numbers. They will then be better equipped than if they had only received the scanty tuition in the subject given in the ordinary curriculum. The *National Medical Journal of China* for October, 1929, is a special "eye number" and contains two articles by Dr. Pillat on the results of treatment of eye diseases by Chinese quacks. Their methods, which embody traditions dating from remote antiquity, frequently inflict quite gratuitous injuries on the unfortunate patients. In spite of the amount of blindness directly traceable to these quacks they will be difficult to supplant, partly on account of the conservative instincts of the native Chinese, and partly owing to the traditional ritual with which the operative procedures are associated—mostly "needlings" either of the eye itself or of points in the face supposed to bear a relation to the eyes. Dr. Pillat calls attention to a peculiarity in Chinese eyes compared with European, in that the upper limbus is frequently exaggerated in sickle form above the cornea so that the shape of the anterior corneal surface is elliptical with a white crescent above, which by the novice may be taken for an arcus senilis, and which affects the landmarks for incision into the anterior chamber when operating for cataract or glaucoma. A third contribution from the same pen concerns the eye symptoms associated with deficiency of vitamin A in adults. In China malnutrition is so common that the disease known as keratomalacia, which in the West is practically confined to infants, frequently attacks adults and is an important factor in the total incidence of blindness. The number also contains articles by native Chinese doctors. C. H. Chow describes some rare injuries of the cornea, including one inflicted by the claws of a cat, and the use of the slit-lamp in discovering the frequency and localisation of lenticular opacities. W. P. Ling writes at length on the ocular findings in infectious diseases, such as typhus, typhoid, dysentery, kala-azar, and pellagra, carefully distinguishing those which may stand in causal relation to the disease.

THE THIRD HASTINGS LECTURE.

Sir Andrew Balfour, Director of the London School of Hygiene and Tropical Medicine, will lecture on "Health and Empire" in the Great Hall of the British Medical Association, Tavistock-square, London, W.C.1, on Wednesday, March 12th, at 8 P.M. The lecture is the third "Sir Charles Hastings Lecture," inaugurated by the British Medical Association for the purpose of offering to the public information by the highest authorities on matters of general public health interest. The first lecture was given on Jan. 24th, 1927, by Lord Moynihan on "Cancer and How to Fight It"; the second on March 21st, 1928, by Sir George Newman, on "The Foundations of Health." For the third lecture the chair will be taken by Lord Riddell, President of the Royal Free Hospital, and after the lecture relevant questions in writing will be invited. Admission will be free, by tickets obtainable on application to the Financial Secretary, British Medical Association House, Tavistock-square, London, W.C.1. Seats not occupied by ticket-holders by 7.50 P.M. will be available for other members of the public.

THE GROWTH OF CHILDREN.

Dr. Gustav Nylin has lately published[1] some observations on the growth of groups of children during a year. His data include estimations of height and weight, the standard metabolism, and the oxygen capacity of the blood, and his material consisted of Swedish school-children of various ages during the years 1926–27 and 1928–29. The measurements of height and weight were made with great accuracy under controlled conditions, the children being always examined at the same time of day so as to obviate error due to the normal daily variations. The basal metabolism was estimated by Krogh's apparatus; the hæmoglobin was estimated at the same time, and the oxygen capacity of the blood was calculated indirectly from this. The results showed that in children of varying ages there is a periodicity of growth during the year, the height increase exhibiting two maxima, of which the larger is from March to May, and the smaller from November to January. The two minima are thus from September to November and from January to March. On the whole it was found that increase of weight varied inversely with increase of height, so that a maximal rise in height coincided with a minimal rise in weight. Besides this periodicity, weight and height in boys showed a periodicity which Nylin terms endogenous; he finds that periods of increased growth tend to be followed by corresponding periods of decrease. Standard metabolism for children round about the age of six years has a periodicity, closely connected with that of height increase, in that during such periods the metabolism rises. It was noted, in the case of one child who was very carefully studied, that a close connexion exists between height increase and metabolism, for both were found to be maximal at the same time of the year and this was when sun radiation was also maximal. Corresponding variation in the oxygen capacity of the blood was also found in school-children of all ages, the minimum occurring during the dark period of the year and the maximum during the light. The latter, however, appeared several months later than the corresponding maximal and minimal metabolic variations. To test the theory that light is one of the causes of height increase, Nylin made some separate observations on a large group of children who were exposed to mercury-vapour lamps and found that such irradiation appeared to stimulate growth in height. These results are of interest in view of the recent observations in England.

SOCIAL HYGIENE.

AMONG those affected by the new Local Government Act is the British Social Hygiene Council,[1] which will no longer receive a central grant from the Ministry of Health but will depend on the subsidies which local authorities see fit to give. Appeals for such amendments of the Bill as would have safeguarded the work of the Council were not successful, but a strongly worded circular was issued to local authorities by the Minister, pointing out the necessity for contribution to propaganda from a central fund. A final grant of £12,000 has been made by the Ministry, but contributions from the local authorities will not be received until December, 1930, and the period between April, 1930, and the following December will have to be covered by voluntary subscriptions amounting, it is estimated, to £5000. The British Social Hygiene Council considers that it would be a failure in public duty to cut down expenditure during these critical months, but should the contribution of the local authorities prove to be inadequate, and should additional voluntary funds not be forthcoming, this policy will have to be reconsidered, to the detriment of a valuable service. A resolution was passed by the Council in 1929 asking that the Parliamentary Committee should consider the possibility of amending the Insurance Acts in such a way that approved societies shall be able to contribute to funds for health education under the sanction of the Ministry of Health. Should this amendment be passed it would open a valuable source of income to the Council.

The decrease in the incidence of venereal diseases during the last few years may at least in part be attributed to the work of the Council. In the Report for 1929 it is stated that the incidence of new infections with syphilis in the Army (an index of that in the civil population) was 9·8 in 1921, and only 2·6 in 1926. The report goes on to emphasise the great value of propaganda in warning the public of the dangers of venereal infection, and in bringing infected persons early for treatment. There has been in the past much difficulty in gaining for this unpopular branch of health propaganda the publicity it requires, but of late years the press has been more ready to lend its coöperation by giving prominence to the advertisements of the Council. Films and lectures have been valuable, and it is noticeable that the showing of a film is often followed by increased, and more prolonged, attendance at the centres. A sympathetic medical officer and almoner can do much to ensure the return of patients who have once attended. One of the effects of propaganda is to bring up for examination those who have been exposed to infection, many of whom are free from venereal disease; an opportunity for advice on prevention is thus offered. Many women infected by their husbands after marriage may be ignorant of their condition, or may object strongly to the thought of attending public centres. It would be advisable for such women to attend clinics run in conjunction with infant welfare centres, and provision should be made for this where possible. Distribution of propaganda to adolescent persons and to children presents a separate problem. It is not thought desirable to teach sex hygiene in school classes, and the Council aim to approach children through parents and teachers, who should attend suitable conferences and lectures. Children leaving school might be addressed, and shown such of the social hygiene films as might be considered advisable. Leaders of clubs and socials should have an adequate knowledge of the physiology and psychology of adolescence, and should coöperate with suitably qualified lecturers to provide instruction on sex for the members of the club. Mentally defective persons are liable to contract venereal diseases early, and to add dangerously to their dissemination. The Council urge that under the new Act the local authorities should provide suitable accommodation for this group and also for "border-line" cases. The work of the Council, carried on in centres throughout this country, as well as overseas in India, New Zealand, Australia, South Africa, and elsewhere, has included the efficient treatment of all cases presenting themselves, as well as a determined publicity campaign. The results achieved, on which the Council has every hope that it can yet improve, are due largely to a well-directed expenditure on propaganda, and adequate support of this policy should be a serious concern of the local authorities under the new Act.

---

[1] Fourteenth Annual Report of the British Social Hygiene Council (Incorporated), Cartaret House, Cartaret-street, S.W.

THE DEFINITION OF DRUGS FOR PURPOSES OF MEDICAL BENEFIT.

ABOUT a year ago an advisory committee was appointed to consider and report to the Minister of Health upon questions referred to them as to the definition of drugs or medicines for the purposes of medical benefits under the National Health Insurance Acts. This committee, over which Dr. D. G. Greenfield presided, have now issued two reports. The first defines their memoranda of reference; they were invited to indicate that each of the substances and preparations referred to them was either *(a)* never a drug, *(b)* always a drug, or *(c)* sometimes a drug. Their second charge was to consider and advise what action should be taken with respect to (1) the practitioner, (2) the chemist, (3) the insurance committee, and (4) the insured person when substances coming under the first or third of these classes were prescribed for insured persons. They have suggested regulations which provide that an insurance committee shall have power to recover from a practitioner the cost of any substance prescribed which is *not* a drug or medicine, and shall pay the amount so recovered into the Chemists' Fund. The rest of the proposed regulation makes provision for the course of action to be pursued in cases where doubt arises, which should be referred ultimately to referees (two practitioners) nominated by the Minister. The second report gives the categories into which substances so far submitted have been placed.

THE Milroy Lectures of the Royal College of Physicians of London will be delivered at the College at 5 P.M. on Feb. 27th and March 4th and 6th by Dr. J. Alison Glover, a medical officer of the Ministry of Health. His subject will be the Incidence of Rheumatic Diseases, and any practitioner will be admitted on presentation of a visiting card.

THERE will be general regret at the announcement, made on this page, that Air Vice-Marshal David Munro, Director of Royal Air Force Medical Services, is retiring at the end of this month. Air Commodore John McIntyre has been selected to succeed him. Air Vice-Marshal Munro is taking up the appointment of secretary to the Industrial Health Research Board, under the Medical Research Council, in succession to Mr. D. R. Wilson, who has lately been appointed Deputy Chief Inspector of Factories at the Home Office.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Lt. Comdr. W. A. Jolliffe to rank as Surg.-Comdr.

Surg.-Lt. T. F. Barlow is transferred to the Permanent List.

ROYAL ARMY MEDICAL CORPS.

The undermentioned relinquish their appointments: Lt.-Col. G. A. D. Harvey, R.A.M.C., Asst. Dir. of Hygiene, War Office; and Maj. J. W. L. Scott, R.A.M.C., Dep. Asst. Dir.-Gen. A. Med. Servs., War Office.

The undermentioned appointments are made: Maj. W. B. Purdon, R.A.M.C., to be Asst. Dir. of Hygiene, War Office; and Maj. A. D. Stirling, R.A.M.C., to be Dep. Asst. Dir.-Gen. A. Med. Servs., War Office.

The undermentioned Lts. (on prob.) are confirmed in their rank: J. G. Black, D. A. O. Wilson, T. R. J. P. Kerwick, C. A. Levy, S. W. K. Arundell, and A. H. Weston.

TERRITORIAL ARMY.

Capt. C. Helm (Lt.-Col. Res. of Off.) to be Maj.

Lts. A. O'Hanlon and H. A. C. Gregory to be Capts.

The King has conferred the Territorial Decoration upon the undermentioned Officers: Lt.-Col. George Herbert Rae Gibson; and Majs. Arthur Morrell Johnson, Clement Arthur Webster, and James Alwin Colville Scott.

ROYAL AIR FORCE.

It is announced that Air Vice-Marshal D. Munro, C.B., C.I.E., Director of the Royal Air Force Medical Services, will be placed on the retired list at the beginning of next month, when he will be succeeded by Air Commodore John McIntyre, M.C.

Air Vice-Marshal D. Munro entered the Indian Medical Service as a Lieutenant in 1902. During the war he served in France and the Middle East, and besides being decorated with the C.I.E. was twice mentioned in despatches. In December, 1919, he relinquished his commission in the Indian Medical Service and was granted a permanent commission in the Royal Air Force Medical Service on taking over the duties of Principal Medical Officer, Headquarters, Royal Air Force, India. He was promoted to the rank of Air Commodore and appointed Director of Royal Air Force Medical Services in November, 1921, and has held this appointment since that date. He was made a Companion of the Order of the Bath in 1924, and in the following year was promoted to the rank of Air Vice-Marshal and also appointed an Honorary Surgeon to His Majesty The King.

Air Commodore J. McIntyre joined the Royal Army Medical Corps as a Lieutenant in December, 1915, and for his services during the war was awarded the Military Cross. On the formation of the Royal Air Force in 1918 he was granted a temporary commission as Major, and employed on medical staff duties at the Air Ministry. In August, 1919, he accepted a permanent commission in the Royal Air Force Medical Service, and subsequently served as Principal Medical Officer to the R.A.F. commands in India and at Halton. He was promoted to the rank of Group Captain in July 1927, and last year to the rank of Air Commodore.

A. H. Barzilay is granted a short service commission as a Flying Officer for three years on the active list, and is seconded for duty at the Royal Southern Hospital, Liverpool.

RESERVE OF AIR FORCE OFFICERS.

Flying Officer T. Glynn relinquishes his commission on completion of service.

INDIAN MEDICAL SERVICE.

Capt. J. W. F. Albuquerque to be Maj.

J. A. W. Ebden to be Capt. (on prob.).

Lt.-Cols. J. W. Barnett and F. H. Stewart retire from the Service.

DEATHS IN THE SERVICES.

Lieut.-Colonel William Coates, late I.M.S., who died at Hove on Feb. 11th, aged 78, was a graduate of the Royal University of Ireland, where he obtained the M.D., M.Ch., in 1876. He served throughout the Afghan War of 1878–80 and was present at the capture of Ali Musjid at the battle of Charasia and at the occupation of Kabul. He was one of the medical officers on the march of Roberts from Kabul to Kandahar (mentioned in despatches, medal with clasp and bronze star). He also served in the Mahsood Wuzeeree Expedition of 1881, and subsequently was transferred to civil surgeoncy work. For some years he was stationed at Lahore. He retired from the service in 1907.

Surgeon Lieut.-Commander Archibald Primrose Anderson-Stuart, R.N., who died at Deal on Feb. 16th, aged 34, was the eldest son of the late Sir Thomas Anderson-Stuart, of Sydney, N.S.W. He was a graduate of Sydney University and became a Surgeon-Lieutenant in the Royal Navy in 1923. After serving in the East Indies on the flagship of Admiral Sir Herbert Richmond, he was appointed to the Royal Marine Infirmary at Deal. In 1928 he served in the battleship *Benbow* in the Atlantic Fleet, and later in the cruiser *Caradoc*. He became Surgeon Lieutenant-Commander last year.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCXCIX.—TREATMENT OF BENIGN UTERINE HÆMORRHAGE AT THE MENOPAUSE.

In the normal menopause the periods either cease abruptly or become gradually more or less frequent, the loss varying in amount, until within a few months there is complete cessation of menstruation. Any excessive loss, occurring either periodically or extending over long periods, must be considered as pathological, and a careful examination and diagnosis of the general and local condition should be made immediately rather than delayed until a severe secondary anæmia or other symptoms develop. Unfortunately, a not uncommon cause of hæmorrhage occurring at the menopause is carcinoma of the uterus or its adnexæ, and it is of first importance, by means of a pelvic examination or a diagnostic curettage, to exclude its presence. In this article benign hæmorrhage alone is considered. In dealing with the various methods of treatment it is usual to group uterine hæmorrhages under various headings according to their cause. There are, however, so many varying opinions on causation and pathology that for practical purposes it is simpler to consider treatment under two headings: (1) hæmorrhage occurring in the absence of any obvious abnormality of the genital organs; (2) hæmorrhage due to non-malignant pathological conditions of the uterus and adnexæ, such as hyperplasia of the endometrium or fibromyomata or adenomyomata of uterus.

HÆMORRHAGE IN THE ABSENCE OF OBVIOUS ABNORMALITY.

Hæmorrhage occurring in the absence of any obvious abnormality of the genital organs may be due to: (*a*) deficient muscular contraction, (*b*) disturbances of the circulation, (*c*) functional disturbances of the ovary.

(*a*) *Deficient muscular contractility of the uterus*, the "metropathia hæmorrhagica" of Aschoff and Pankow, is characterised by a large, rather soft uterus, with thick walls. Theilhaber explains such hæmorrhages as due to a localised uterine arteriosclerosis, or "insufficienta uteri," accompanied by compensatory hyperplasia of the connective tissue.

(*b*) *Disturbances of the circulation* such as occur in patients suffering from heart, kidney, or lung disease. An unrecognised syphilis may be responsible for serious hæmorrhages which clear up with suitable antisyphilitic treatment. Certain blood dyscrasiæ, such as purpura, or calcium deficiency, may give rise to hæmorrhage at the menopause, also faulty blood coagulation.

(*c*) *Functional disturbances of the ovary*, such as the persistence of the Graafian follicles associated with absence of the corpus luteum, may lead to hæmorrhage. This condition is probably due to some endocrine disturbance or hormonal deficiency, and causes usually a severe metrorrhagic hæmorrhage.

Accurate diagnosis is in no field of medicine more important than here. The history of the patient, together with an examination of the heart, lungs, and abdomen, and the urine, a careful vaginal or rectal examination, and, if necessary, a diagnostic dilatation and curetting, should indicate to which of the three causes the hæmorrhage is due:

(*a*) If there is a decrease in the muscular tone of the uterus, and deficient muscular contraction, a course of ergot is indicated. This may be given as—

Normal liquid extract of ergot (physiologically standardised) in 20 min. doses three or four times daily, just before and during the periods. Or as—

"Ergot aseptic," made up in 1 c.cm. bulbs, representing ergot 2 g., and given hypodermically night and morning. Ernutin, 30–60 min. per os t.d.s., or 5–10 min. hypodermically. Tab. ergotininæ citras, gr. 1/200 hypodermically t.d.s., or tyramine, gr. ½ tablets hypodermically. Hydrastin also increases uterine contraction and may be given with or without ergot, either as liq. extract in 30 min. doses, or in a pill as hydrastin, gr. ½ or 1.

Cotarnine hydrochloride (stypticin) in tabloids, gr. ½, four times daily, or styptol tablets, gr. ¾ four times daily, are great standbys, and sometimes succeed when ergot fails. And lastly—

Pituitary gland extract (post. lobe), in sterules 0·5–1 c.cm., containing 5–10 units respectively bis die, intramuscularly.

(*b*) Here the primary cause must be dealt with and appropriate treatment prescribed. If the calcium content of the blood is deficient, a diet rich in calcium salts should be given—e.g., green vegetables, farinaceous foods, buttermilk, &c. Salt should be used sparingly, and calcium lactate, grs. 60, given daily for three weeks at a time (a teaspoonful dissolved in a glass of hot water, and one-third taken at breakfast, lunch, and dinner is a useful way of prescribing it). If the hæmorrhage is due to faulty blood coagulation, any of the commercial forms of thrombin may be injected subcutaneously. (To ascertain the coagulation time, take 5 c.cm. of blood from the arm into a test-tube, and compare with the mean time of normal blood taken under the same conditions, which does not exceed ten minutes.)

(*c*) Here *organotherapy* is indicated. There is still considerable doubt as to whether excessive menstruation is more likely to be associated with hyper- or hypothyroidism, and what part the pituitary thymus and suprarenals play. Preparations of *ovarian extract*, injected intramuscularly, and with or without pituitary or thyroid, or of *corpus luteum* may be found useful.

HÆMORRHAGE DUE TO NON-MALIGNANT PATHOLOGICAL CONDITIONS.

The commonest pathological conditions to which hæmorrhage may be due are: (*a*) glandular hyperplasia of the endometrium, and (*b*) fibromyomata of the uterus and adenomyomata.

Glandular Hyperplasia of the Endometrium.

In this condition the uterus is somewhat enlarged and hard, the bleeding is severe, and either menorrhagic or metrorrhagic in type. We have a sure and safe treatment in either deep X ray therapy or radium.

Deep X ray therapy is perhaps of greater service in this type of disease than in any other. As developed and practised at the present time it is unrivalled both for its certainty in producing an artificial menopause and its freedom from any serious after-effects. With one of the new types of apparatus, such as the 1929 Stabilivolt, the treatment can be completed in from 48 to 90 minutes either at one sitting, or if it is preferred, half the treatment can be given on two consecutive days.

The best time to choose is within ten days of the last menstrual period, the Graafian follicles being then at a younger state of development and more easily affected by X rays. The patient should be given an aperient the day before the treatment and a rectal washout on the evening before. The urine should be systematically examined, since the presence of albumin or sugar materially affects the dosage. The temperature should be normal. It is important that the skin of the abdomen and dorsum should be free from any eruption. The bladder should be empty, and the patient should have had only a light breakfast of tea and one slice of toast one and a half hours before treatment. It is desirable that the X ray room should be large, warm, airy, light, and ventilated in such a way as to secure a constant change of air in the room. The couch should be comfortable, and the lead rubber sheeting should be so arranged that only the area to be irradiated is exposed at one time.

If the uterus is only very slightly enlarged, four areas of 6 by 8 cm., one anterior and one posterior to each ovary, with an interval between 4 cm. wide, using 180,000 voltage, three M. amps. in the secondary current, a filter of ·5 Cu. + 2 al., a U.S.D. of 12·15 min., and a depth dose of 18·5 per cent. will be sufficient to ensure a permanent sterility in a woman of 45 years of age, provided her Baudelocque diameter is not more than 20 cm.; if it is, an extra field is desirable.

After such a treatment the patient menstruates as usual once, in a small percentage of cases twice, after which she shows some vasomotor disturbances such as "flushes," although these as a rule are less severe than those occurring in a natural menopause. Partly due to the cessation of the periodic hæmorrhages, and partly due to an unknown factor described by some authorities as the "Steinach effect," possibly an auto-oöphortherapy, caused by the ovaries and uterus remaining in loco the patients not only quickly regain their normal health, but in a very large percentage report "that they feel ten years younger."

Radium has much the same action, and will, in suitable dosage (approximately 1200 mg. hours), induce an artificial menopause. Indeed, it may also be called a specific for the treatment of climacteric hæmorrhage due to glandular hyperplasia of the endometrium.

Under an anæsthetic, and with surgical asepsis, posterior and anterior vaginal speculæ are inserted, the cervix carefully cleansed with weak lysol or acriflavine. It is important that no antiseptic containing a metal is used, on account of possible secondary radiation. The anterior lip of the cervix is grasped with a volsellum, and an intra-uterine sound inserted, to ascertain the length and direction of the uterine cavity. The cervical canal is then carefully dilated up to about No. 10 Hegar, and the radium introduced.

A dose of from 50 to 75 radium element is usually sufficent. This is best made up in two or three needles, each containing 25 el. and put in containers of platinum 1 mm. thick, placed in tandem in a rubber case or tube, and left in situ 22 hours. Thus a dose of 1200–1500 mg. hours is usually given.

Fibromyomata of Uterus and Adenomyomata.

For this condition we have the choice of two forms of treatment: (1) Surgical—myomectomy, or subtotal or total hysterectomy. (2) Deep X ray therapy, and in a small percentage of cases, radium. In my own series of 445 cases I did a hysterectomy or myomectomy in 231 cases, deep X ray therapy in 206, and used radium in eight.

A preliminary examination under an anæsthetic, and a diagnostic dilatation and curettage may be indicated.

1. *Surgical interference* is imperative under the following conditions: (1) a tumour reaching above the umbilicus; (2) pedunculated subperitoneal tumours, or (3) submucous tumours; (4) in the presence of tumours of the ovaries; (5) when degeneration is suspected, either necrobiotic or carcinomatous or sarcomatous; (6) in all cases of doubtful diagnosis.

2. *Deep X ray therapy* is the treatment of election where the tumour is interstitial, the hæmorrhage severe, and the diagnosis clear. The technique varies only slightly from that given above. If the tumour is big, larger fields and a greater focal distance to increase the depth dose are required, to bring about a reduction in the size of the tumour, as well as the cessation of the hæmorrhage.

3. *Radium* is used with success also in a small proportion of such cases if the following contra-indications, in addition to those mentioned in connexion with X ray therapy, are remembered—namely: (1) The presence of submucous or interstitial fibroids which encroach on the endometrium. Here the necrosis caused by the radium may lead to a long intractable uterine discharge, septic absorption, and general ill-health. (2) The presence of a pelvic infection, whether recent or of long standing.

In deep X ray therapy and radium the rays are essentially the same, for in radium we have a natural source, and in X rays an artificial source of Gamma rays. Although radium is invaluable in the treatment of certain types of cancer, especially in cancer of the cervix, X ray therapy is greatly to be preferred in the treatment of fibromyomata of the uterus.

It can produce the same results in this field as radium, whereas the converse does not hold good. In proper hands it is entirely free from danger, whereas radium may produce febrile or inflammatory reactions, and occasionally even suppuration, complications, which are as a rule transitory and not of a serious nature, but which in exceptional cases and in the proportion of 3 per 1000 (Béclère and Regaud) prove fatal. In addition, we must remember that radium therapy is by no means free from discomfort and pain. Its application entails an anæsthetic, confinement to bed, and the presence in the uterine canal of metal tubes for at least 22 hours. X ray treatment, on the other hand, is rapid (40–90 minutes), involves no anæsthetic and no after-treatment. The patient, if she is a worker, need not take special sick leave, unless she is suffering from the effects of the anæmia caused by the menorrhagia. It is sure—the effects are gradual, one or possibly two monthly periods occurring after treatment, the menopausal symptoms (flushes, &c.), coming on slowly, and being less than those occurring at the natural menopause. It is safe—there is no mortality, no resulting endometritis or dyspareunia, no alteration in sexual characteristics. The only disadvantage is the expense of the apparatus and its upkeep, and the skill, knowledge, and care needed in its application.

LOUISA MARTINDALE, M.D., B.S. Lond.,
Senior Surgeon, New Sussex Hospital, Brighton;
Surgeon, Marie Curie Hospital, London.

Special Articles.

THE DEATHS OF BRITISH MERCHANT SEAMEN IN 1928.

BY FLEET SURGEON W. E. HOME.

THE yearly Board of Trade Return[1] which includes the deaths on vessels registered in the United Kingdom in 1928 (classified they are in accordance with the short list of the Registrar-General with the same modifications as in 1927), tells us that the "first crews" of vessels were, British, in sail, 1600, and in steam and motor vessels, 162,700, making 164,300 British in all, with 18,900 foreigners and 56,500 Lascars, giving a total of 239,700. The Return indicates that this number, the "first crews," furnishes an approximate basis for estimating the variation in the extent of the risks from year to year, though no helpful comment on the variation is put forward. But in the last census of seamen, taken on March 31st, 1926, it was found that the British seamen employed on that day were 81 per cent. of those stated that year among the "first crews," and that the Lascars were 91 per cent. of their figure, the remainder being no doubt on leave or waiting for ships, or unemployed. So, to get a truer idea of the population at risk from day to day, to represent the daily ration strength, it will be better to take these proportions of the "first crews," in round numbers, for British, 133,000, for Lascars, 51,000, and with them to calculate death-rates to indicate if health is improving at sea. The resulting figures though not meticulously correct will at least give us a first significant figure that will be reliable, and the Board of Trade (since 1920) does not even do so much for us as that.

The total British deaths were 861 (6·45 per 1000), of which 403 (3·02) were attributed to disease, 19 (0·14) to alcohol, and 430 (3·20) to violence, of them

---

[1] Return of Shipping Casualties and Deaths on Vessels registered in the U.K., as far as reported to the Board of Trade in the year, 1928. London: H.M. Stationery Office. 1929. Pp. 8. 2s.

29 (0·22) to suicide, 379 (2·85) to accidents, almost the same figures as in 1927. The total Lascar deaths were 236 (4·63), of which 168 (3·29) were thought due to disease, none to alcohol, to violence 68 (1·33), of which 16 (0·31) to suicide, 43 (0·84) to accidents, the small decrease chiefly in deaths from disease. About half the British deaths were due to accidents, but only a fifth of those of Lascars. The chief named individual causes of death from disease were, for British seamen, pneumonia, 51 (0·38), an increase, from tubercle of lung, 23 (0·18), a decrease, and enteric fever, 21 (0·16); for Lascars, pneumonia, 42 (0·82), an increase, for tubercle of lung, 23 (0·45), a decrease. It will be noticed that the death-rates for pneumonia and tubercle of lung for Lascars (0·82 and 0·45), who need only have 72 cubic feet of space on their sleeping decks, are roughly double of those (0·39 and 0·18) that occurred among British seamen whose least allowable cubic space is 66 per cent. greater (120 cubic feet). During the last five years (1924–28) deaths from tubercle of lung have been separated in the Return from deaths from tubercle "other," and these having been added together and divided by the five-year totals of "first crews," we find that the death-rate in the five-year period has been, for pneumonia, in the neighbourhood of 0·3 for British, 0·7 for Lascars; for tubercle of lung, British, 0·16, Lascars, 0·7 per 1000, the Lascars having a pneumonia rate twice and a phthisis rate four times that of the British. The true death-rates were really larger, but not materially different. It may be worth while to look at the change in 30 years; then we have, per 1000, "first crews,"

		1901–02.	*1928.*
Pneumonia	British	0·3	0·3
	Lascar	0·9	0·7
Tubercle (all)	British	0·3	0·2
	Lascar	1·1	0·7

from which it appears that hygiene has done more in 30 years for the Lascar than for the British sailor, and more against tubercle than to prevent pneumonia.

It will be observed that the average number of British seamen employed daily, 133,000, is midway between the number employed in the Army in 1928, 183,333, and in the Navy in 1927 (latest year available), 93,230. The death-rates are, Army, 2·50; British merchant seamen, 6·45; Navy, 2·15, and by violence, causes other than disease or alcohol, Army, 0·89; British merchant seamen, 3·29; Navy, 0·77. Merchant seamen being older have a higher death-rate of course. So far as can be calculated, the middle or average age is, in the Army, 24; in the Navy, 25½; in the British merchant service, 30 (the highest group in the Army statement is "40 years and over," in the Navy, "45 and over," in the census of seamen, "50 and over." Why, by the way, do not they all state their ages in the five-year periods of the Registrar-General? What is the practical use of the grouping of the census of seamen "under 18," "18–24," "35–49," except to hinder research?); still when every allowance is made the death-rates of the British merchant seamen do seem excessive, as indeed was said in the Registrar-General's last Decennial Supplement, Appendix B.

The Return tells of the deaths of 403 seamen from disease, of 379 from accidents. The Board of Trade makes no attempt to discuss or explain these facts, and indeed it has no staff for that purpose, but it assures us that if need should arise it will ask the Ministry of Health what to do. Does it not seem to professional, indeed to intelligent lay, opinion that it would be an advantage if the Board, having received the reports of deaths of seamen, at once sent them on to the Ministry, whose expert staff would more quickly realise any need for special attention or action than would the exceptionally intelligent but professionally uninstructed staff of the Board of Trade? Such action has been from time to time invited by the Royal Sanitary Institute, and by others, but nothing seems to happen, and death-rates do not fall as they should.

It will be noticed that, in 1928, 379 British seamen died from accidents. Of these and of the efforts the Board doubtless made for their prevention in future, no mention is made in the Return or elsewhere that I can find. How differently another department manifests its concern in such cases. In 1928 in the factories and workshops of Great Britain there occurred 953 fatal accidents, about which, and the others associated, the Home Office, which has a medical staff, published a book (Cmd. 3360 of 1929) of 150 pages, one page for every six fatal accidents, with statements of contributory causes, prevention, fines, and so on; there were three and a half pages relating to the 100 fatal accidents in docks, as far as dockers were concerned, and 25 pages were included of medical comment by the Senior Medical Inspector, on reading which one feels inclined to ask, With their scanty facilities for washing before meals, are there no seamen suffering from lead poisoning from painting at sea? They are found with difficulty ashore. Are they ever looked for afloat?

In fact, when one remembers that the seamen are in the care of the Board of Trade that cannot tell us their death-rate from year to year, that evidences no intensive care of their accidents or extension to them of the care given to most other workmen, one thinks a little bitterly that this is probably because the seamen, being mostly abroad on any one day, can rarely vote. Is the medical profession satisfied that the health of the seamen is properly safeguarded? Does the seaman get a square deal?

THE LOWER END OF THE ŒSOPHAGUS.

DR. MOSHER'S SEMON LECTURE.

THE Semon Lecture of London University for 1929 was delivered on Dec. 5th, in the Barnes Hall, by Dr. Harris P. Mosher, Professor of Laryngology at Harvard University, the chair being taken by Dr. Dan McKenzie, President of the Laryngological Section of the Royal Society of Medicine. He took as his subject the lower end of the œsophagus at birth and in the adult. The following is an abstract of Dr. Mosher's remarks, which will appear in full later in the *Journal of Laryngology and Otology*.

Anatomical Relations.

The lower end of the œsophagus is occasionally narrowed by the pressure of liver or spleen, either of which may almost close the lumen. At birth there is a long liver-tunnel and often a spindle-shaped dilatation in the lower third bounded above and below by the lungs and liver respectively. A circular narrowing as the œsophagus passes through the crura is very common and is usually accompanied by a sharp spur, which becomes a definite ring-like fold when the stomach turns sharply upwards. The most striking abnormality at birth is a marked narrowing of the cardia. All adult abnormalities, including pouch, may be found at birth. The œsophagus is surrounded by very extensive connective tissue sheath, thicker on the left side and continuous with the lesser omentum and the suspensory ligament of the stomach. These connect it up with the liver and spleen, making possible points of infection. The thickening on the left side may at times be a definite falciform ligament surrounding the left half of the crural opening; this plays an important part in the crural impression found in cardiospasm. One baby showed extensive enlargement of the glands at the bifurcation of the trachea, forming a sheath of glands down to the diaphragm.

A frozen vertical section of a baby at birth shows clearly that the œsophagus comes to a point where it meets the upper edge of the left crus, its angle changing here from transverse to anteroposterior. The terminal portion, the crural arm, is a thin antero-posterior ribbon covered by the left crus. This section explains the appearance seen in X ray films. If there is peristalsis, the fluoroscopic picture of a œsophagus swallowing barium milk looks like a string of stubby, badly formed sausages. In cases of cardiospasm the barium accumulates in the lower end in a thin awl-like point and a small stream trickles into the stomach when the diaphragm ascends. If the patient takes a deep breath, about half an inch of the pointed end of the œsophagus is suddenly cut off. This is due to the closure of the upper part of the crural angle. The form of the sling made by the crura and the amount of support it gives to the œsophagus varies greatly. Normally the two crura come together sharply before they overlap, but sometimes the angle is wide and little support is afforded. In a dilated, sagging œsophagus the wide crural sling may have a clothes-line effect, and bring about the backward bend which is such an important factor in obstruction.

There is a slight and constant thickening of the œsophageal muscles on the left side at the lower end. A cardiac sphincter is often present and consists of a crescentic enlargement of the terminal muscle-fibres. There is a pronounced thickening of the muscular coat where the gastric mucosa begins. The injection of a baby's stomach with wax explained the horizontal fold often seen beneath a gas bubble in the X ray of cardiospasm. It is due to the transverse colon.

Microscopical Findings at Birth.

The connective tissue in the cone of the diaphragm is like a pile of brushwood waiting for the match of infection, and the œsophagus may be infected before birth. This infection plays the major part in cardiospasm. One baby showed the stomach glued to the left side of the œsophagus by dense adhesions, an invagination of the lower end of the œsophagus into the stomach, a great thickening of the crural fold, and an ulcer of the lower end of the œsophagus. An incipient fibrosis was revealed by a great increase of the submucosa and a marked thickening of the circular muscle bundle at the point where the stomach mucosa joined that of the œsophagus. There are two sets of glands in the œsophagus, an upper set between the cricoid and the bifurcation of the trachea and a lower set at the lower end. The upper set are often found in clusters of some size, and these patches are very liable to ulceration. In the last half inch of the œsophageal mucosa there is often a bluish, ring-like band which contains many glands.

Occasionally an œsophagus shows marked segments at the lower end, a structural weakness which adds to the mechanical difficulties of this part and may be a cause of pouching. I believe that ulcer at the lower end of the œsophagus is more common than is realised and is often the cause of spasm. Old ulcers are revealed in the X ray by rib-like projections. A scorbutic guinea-pig may show almost complete occlusion of the œsophagus from hyaline material; the possible effect of vitamin deficiency on the œsophagus stirs the imagination. The involvement of Auerbach's plexus in cardiospasm is secondary and late and accounts for the rare appearance of peristalsis. The plexus is very resistant to acute infection.

The Barium-striped Bag.

Extraordinarily little pressure is needed to overcome the crura in cardiospasm; two pounds will do it and three or four pounds will dilate the crural crease. Spasm is the natural reaction of any part of the alimentary tract to irritation. The use of the barium-striped bag has made many points clear. It is a modification of the Sippy bag by the addition of four barium lines, so that the shape that the bag assumes can be seen through the fluoroscope. I also use a flexible finder about four or five inches long with a heavy tip one centimetre in diameter. Only once has a finder of this size failed to pass into the stomach in cardiospasm. Where the ordinary X ray shows a small awl-like point, the striped bag shows either a waist-like narrowing in the cone of the diaphragm or a large annular stricture opposite the crural opening. A Seidlitz powder is useful for making a gas bubble in the stomach. As a routine I begin by giving the patient a few mouthsful of barium milk to find the fluid level and then give the powder, upon which the barium passes into the stomach—unless the constriction is very tight—leaving the œsophagus relatively clean for the passage of the bag. The findings in cardiospasm are very constant, either a waist-like narrowing of the lower end or two dents opposite each other, the left being larger and blunter. When the patient drinks barium and then takes a forced inspiration there is a much larger impression in the left wall than in the right. This, like the left dent seen with the bag, is the impression of the left crus. The smaller sharper dents, giving the impression of a string-like stricture, are produced by a fibrosis of the fascial covering of the edge of the crura together with connective tissue changes in the œsophageal wall. Adhesions of the diaphragm to the basal pleura are common in cardiospasm and always on the left side; they show up as saw-tooth projections from the upper surface of the diaphragm and indicate a previous chest infection as the cause of the cardiospasm. Pains suggest ulcer or spasm, or both. Ptosis of the diaphragm and the stomach are so common as to be of little importance but may play a part in cardiospasm, as the crural opening falls with the diaphragm. The crural crease in the œsophagus may be found in these cases above the dome of the diaphragm, since it is a more or less fibrotic change in the wall of the œsophagus. Fibrosis of the crural ring, due to low thoracic or high abdominal infection, is the great cause of cardiospasm. Associated with it in old cases there is a backward bend and fibrosis of the terminal portion and a degeneration of Auerbach's plexus. As a result of such infection, transferred from adjacent glands, the œsophagus at or before birth may show a localised or generalised hypertrophy, ulceration, and adhesion.

MEDICINE AND THE LAW.

Manipulative Treatment and Pleurisy.

AT a Liverpool inquest, held at the end of last month upon the death of Mrs. Webster-Jones of Mossley Hill, it appeared that the husband had been unaware of his wife's illness until a few days before her death. Prof. J. McFall of Liverpool University, who conducted a post-mortem examination, considered that the deceased had been suffering from pleurisy for about a month and that there were indications of there having been peritonitis for over a week. Less than a week before death occurred Mr. Patrick Saul, an osteopath of Wavertree, was called in. He stated at the inquest that he held the diploma of the British School of Osteopathy, London. He had found Mrs. Webster-Jones suffering from a septic throat; complications set in and he recognised pleurisy. The coroner, Mr. G. Cecil Mort, asked Mr. Saul how far the manipulative treatment which he practised extended; what limits to it were there, if any? Mr. Saul replied that according to the ruling of osteopathic schools of thought in America there were no limits to the treatment. Prof. McFall in his evidence said there was no doubt, from his point of view, that the deceased's condition had been quite neglected. The coroner thereupon asked him whether, in spite of the neglect, there was anything done to his knowledge which in any way hastened the death. The witness replied in the negative. The husband had previously stated that both he and his wife were perfectly satisfied with Mr. Saul's treatment.

A verdict of death from natural causes was returned. "In this country," said Mr. Mort in the course of his summing-up, "the registration of medical men is adopted for the protection of the public; as long as that is recognised, the responsibility rests with the public as to whom they go to for medical advice."

Fresh Inquest Ordered: Coroner and Witnesses.

Expressly disclaiming any reflection upon the coroner, the High Court on Feb. 11th quashed two inquisitions of Dr. J. Divine, coroner for Kingston-upon-Hull, and ordered new inquests to be held before the coroner for the adjoining Howdenshire division. The judges composing the Court announced that they would take time to consider their judgment upon certain points raised by the proceedings, but, as time was of importance, they announced their decision as to the new inquests forthwith.

Two inquests had been held last December upon the deaths of men named Rispin and Boddy from injuries received when their motor-lorry came into collision with a motor-car driven by Mr. George Walton of Hessle. Each inquest resulted in a verdict of manslaughter against Mr. Walton, who thereupon moved to have the proceedings quashed on the ground of alleged irregularities. The irregularities were set out as follows: (1) that the coroner viewed and discussed a damaged vehicle with a man who subsequently acted as foreman of the jury; (2) that the coroner joined the jury in their inspection and discussion of the damaged vehicle without allowing any other parties to be present; (3) that the coroner failed to direct the jury as to the meaning of manslaughter or as to the degree of negligence required to support such a charge; and (4) that the coroner failed to read over his notes to the witnesses before they signed them. Apart from these possible grounds for reopening the proceedings there was a statement that two fresh witnesses were available, one of them being apparently prepared to say that Mr. Walton was not driving at an excessive speed, the other to say that the brakes of the lorry were not in proper working order before the collision. Dr. Divine dealt in an affidavit with the alleged irregularities. He admitted that he viewed the vehicles with a man who was afterwards a juror, but he denied that any discussion took place either then or when the jury viewed them. He said he had invited the interested parties to be present. He claimed that he had carefully directed the jury and he said that he had read over Mrs. Walton's deposition before she signed it, though he had not read over the depositions of other witnesses, as their evidence was clear, and such reading over was, in his opinion, unnecessary. Finally, while contesting the allegations of irregularity, Dr. Divine explained that he was quite willing to hold a fresh inquest if the Court deemed the evidence of the two new witnesses to be material.

It will be recalled that Section 19 of the Coroners (Amendment) Act, 1926, made it clear that the discovery of new evidence will justify the quashing of an inquisition and the holding of a fresh inquest if necessary or desirable in the interests of justice. The significance of this Section lies in the fact that the coroner himself can now apply for a fresh inquest on this ground, whereas formerly the High Court seldom granted a fresh inquest (under Section 6 of the 1887 Act) unless the coroner had in some way been found at fault. Further comment on the High Court's recent decision is reserved until the Court has delivered its considered judgment. Consisting of Mr. Justice Talbot, Mr. Justice Charles, and Mr. Justice Humphreys, the Court is a remarkably strong one for the purpose, and it may be that the judgment will throw valuable light on the coroner's duty to read over evidence to witnesses, and on the extent to which he may properly be present amongst his jury in the absence of parties whose conduct the jury's verdict may impugn.

A "Sun Room" at Southport.—The Earl of Crawford and Balcarres last week opened a "Sun Room" which has been added to Southport Convalescent Hospital at a cost of over £4000. It takes the form of a large winter garden or palm court, roofed and windowed with vita glass, and will hold 100 patients.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

HUNTERIAN FESTIVAL.

Following the Hunterian Oration (reported fully in another part of this issue) on the afternoon of Feb. 14th, the President and Council of the College entertained at dinner in the Library of the College a distinguished gathering which included Mr. Arthur Greenwood (Minister of Health), Viscount Knutsford, Lord Atkin, the Dean of Westminster, Sir John Anderson, Mr. Justice Hawke, Sir Bannister Fletcher (President of the Royal Institute of British Architects), Sir Arthur Robinson (First Secretary of the Ministry of Health), Mr. Nathaniel Micklem (Treasurer of Lincoln's Inn), Sir David Murray (Prime Warden of the Fishmongers' Company), the Masters of the Drapers', Skinners', Haberdashers' and Apothecaries' Companies, Sir Walter Fletcher, Sir Farquhar Buzzard, Sir Humphry Rolleston, Surg-Vice-Admiral A. Gaskell, Air Vice-Marshal D. Munro, Sir P. Chalmers Mitchell, and Sir Frederic Hallett. The following Members of the Council of the College were also present:—

Mr. C. H. Fagge and Mr. V. Warren Low (Vice-Presidents), Sir Holburt Waring, Sir John Lynn-Thomas, Mr. Ernest W. Hey Groves, Sir Cuthbert Wallace, Mr. F. J. Steward, Mr. R. P. Rowlands, Mr. J. Herbert Fisher, Mr. W. Sampson Handley, Sir Percy Sargent, Mr. G. E. Gask, Mr. W. McAdam Eccles, Mr. Wilfred Trotter, Mr. A. H. Burgess, Mr. Victor Bonney, Mr. G. Grey Turner, Mr. Hugh Lett, Mr. R. G. Hogarth, Mr. R. E. Kelly, and Mr. Graham Simpson, with Sir D'Arcy Power (Honorary Librarian) and Mr. S. Forrest Cowell (Secretary).

Lord Moynihan who presided, in bidding the guests welcome on that evening for their social and academic distinction, offered them the permanent hospitality of the Museum below, should they attain equal distinction in a pathological sense—the gift of true immortality, he called it. He alluded in a few but weighty words to the outstanding need of a centre in London for post-graduate teaching and to the great opportunities for public medicine which were inherent in the provisions of the Local Government Act. Mr. Greenwood, in replying for the guests, said he shared the desire to see such a post-graduate centre an accomplished fact at an early date. London, he remarked, ought to be the greatest home of post-graduate research. Lord Atkin, who admitted frankly as a lawyer "we lag behind you at certain stages," contended with equal frankness that this lag had been unquestionably good for humanity. He laid stress on the importance of medico-legal subjects and put in a plea for a post-graduate institute of medico-legal knowledge. Prof. Thomas Loveday, Vice-Chancellor of Bristol University, in proposing "The Hunterian Orator," spoke of Prof. Groves as a true son of the West country, with distinction both as surgeon and teacher. After dinner the guests scattered to other parts of the College, many of them to the Hunterian Museum which had just been described by the President as the greatest monument ever erected to the honour of a man by himself in his own lifetime.

A New Durham County Hospital.—The Durham County Council and its Public Assistance Committee have decided to build a large central hospital for medical and surgical cases.

St. Bartholomew's Hospital "Lighthouse."—The beacon light which has been placed on the roof of St. Bartholomew's Hospital to call attention to its appeal for a million of money for rebuilding and re-equipment, has been raised 30 feet higher, that its beams may be seen at a greater distance. It has been arranged that very shortly the hospital shall be open free, by ticket, to the public on five occasions for the entire 24 hours. On March 11th and succeeding evenings "The Acts of Rahere," a play illustrative of the life of the founder of the hospital, will be performed in the church of St. Bartholomew the Great.

THE CASE AGAINST THE WIDAL TEST.

To the Editor of THE LANCET.

SIR,—Will you kindly allow me to make some remarks on your leading article under this heading of Feb. 1st? First, I feel that the statement, which you quote, that "the whole enteric group can be differentiated in one dilution without titration of the serums," may have unfortunate effects. May I point out to your readers that the majority of experts do not agree with the statement quoted? For myself, while I admit that the enteric fevers can *usually* (under present conditions) be identified in a single dilution, I hold that in an important minority of cases the additional information gained by titration is indispensable. A good deal more evidence must, in my opinion, be produced in its support before pathologists will be justified in taking what might be termed a retrograde step. The single-dilution method of agglutination, though commonly practised in the infancy of the Widal test, was discarded in favour of a completer titration when experience had been gained of the limitations and pitfalls of the simpler method. In the same way the living culture, a risky and unreliable weapon in all but highly experienced hands, gave way to sterile and standardised suspensions of well-tested properties. Now it is the advent of the "O" type of test that has given the impetus to this movement. "Qualitative receptor analysis" (I do not like either "receptor" or "analysis"), as you have explained, means simply the addition of the "O" test, and the abandonment of the quantitative method.

The new school holds that since the serum of inoculated persons contains no "O" agglutinins, the mere detection of "O" agglutination is diagnostic of infection. This is but a partial truth. Actually the present type of inoculation normally gives rise to titres of "O" agglutination running up to 1 in 200 or 1 in 500 (I have seen traces at 1 in 1000 soon after the second dose), which do not take long to sink below the level (about 1 in 100) of the single dilution recommended for the qualitative test. Thus the residual titre seldom, if ever, interferes with diagnosis in persons whose inoculation is not very recent. But how long will present conditions continue? I have little doubt that in the near future vaccines will be so prepared as to induce as high and permanent an "O" titre as is at present induced for "H." In that case the whole basis of the "qualitative receptor analysis" will crumble, and we shall again be left, as we were in 1914, with serial quantitative measurements as our sole means of establishing a diagnosis in inoculated persons. It is, however, alleged that this latter system is completely vitiated by the "anamnestic reaction," which means that infections other than enteric can cause large rises of the residual titre due to inoculation, and that diagnosis is therefore impossible. Now I submit, Sir, that the importance of the "anamnestic reaction" is very uncertain. True, it has been proved that large rises *can* occur. But there is no evidence that they do so often; indeed, it has definitely been shown that they are rare. This, then, though an important occasional limitation of the method of serial titrations, does not by any means destroy its utility. A high degree of probability in a positive serological result is very useful, even if it contains an element of uncertainty. On the negative side, the value of the method remains undiminished. It is true that serial titrations of "H" agglutinins often fail to distinguish between typhoid and paratyphoid B in triple inoculated persons. But a diagnosis of enteric group infection is of great value. No more than this, indeed, is claimed for "qualitative receptor analysis," when applied to the inoculated.

Quite apart from serial titrations, to deprive oneself of the power of distinguishing between a serum of titre 1 in 100 and another of 1 in 5000 is to limit one's power of diagnosis. For instance, high "H" titres are caused by the specific infection in persons inoculated so long ago that their residual titre has inevitably fallen to quite a low figure—a valuable diagnostic point.

There are other uses for titration. We may find no "H" or "O" agglutination at 1 in 25 at our first test of an uninoculated person, but four or five days later a complete reaction with one or the other suspension at 1 in 50. These two tests together are sufficient for a diagnosis, assuming that standardised suspensions are used. Suppose we had only tried a single 1 in 100 dilution on both occasions? A review of my own records shows me not a few cases in which I should have missed a low-titre provisional diagnosis (subsequently confirmed) if I had not put up 1 in 25 and 1 in 50 dilutions.

Perhaps some laboratories are really unable to cope with the full titration of many suspensions. If so, and if more labour is unobtainable, there are ways of saving time without loss of efficiency. For instance, in some circumstances two or three suspensions may be mixed together. If the result is negative, much labour is saved. Again, a partial titration can be done with two dilutions, as I have recently suggested. This corrects some, though not all of the weaknesses of the single-dilution method. In negative cases time is saved, while positives can, if desired, be further titrated.

I will conclude with two minor points of the many that I should like to discuss. I do not believe that the strain *B. typhosus* 901 is at all unique. There is no difficulty in finding any number of typhoid strains that make excellent "O" suspensions. It is true that the only existing (so far as I know) stable pure "O" culture was obtained by Dr. Felix by accident from that strain—but we shall doubtless get others. Finally, your article suggests (accidentally, I think) that the diagnosis in the case published by Hobson, Stenhouse, and myself in your issue of Jan. 25th was made with a living suspension, whereas it was made with a formolised broth standardised suspension of the "O" strain just mentioned, and checked with an alcohol-treated suspension of the same bacillus.

I hope, Sir, that I have said enough to convey a warning against a hasty and uncritical abandonment of the quantitative method. Every bacteriologist who is in doubt will be able to form his own opinion on the matter if he will continue to titrate, use "O" suspensions (*B. typhosus*), in addition to the usual "H," and see whether, in an adequate series of cases, any one of his dilutions would have given all the results obtainable by titration. I should like to add that the Standards Laboratory at Oxford is about to issue a completely modernised leaflet of Directions for diagnostic agglutination tests.

I am, Sir, yours faithfully,

Oxford, Feb. 13th, 1930. A. D. GARDNER.

THE MEMBERS AND THE COUNCIL OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

To the Editor of THE LANCET.

SIR,—Following the encouragement which those of us who are responsible for a direct move to obtain representation upon the Council of the Members of the Royal College of Surgeons of England have recently met with, we have received promises that should enable us soon to invite from the Members themselves a material expression of their adherence.

On Friday last Prof. Hey Groves, in the Hunterian Oration, referred in generous and valuable terms to our movement. He pointed out that for over 30 years the governing body of the College had been requested to consider the situation, and alluded to the phase of amity and good temper which at last marks the discussion of the question at the annual meeting of Fellows and Members. But he went on to point out that, unless a substantial number of the 18,000 Members record their view that the reform is desired, the Council of the College may well decline to believe that the modern and democratic aspect need be adopted. "The chief thing," said Prof. Hey Groves, "which is needed to bring this about quickly is convincing evidence that the change is desired by the great body of the Members."

A circularising of the Members will shortly take place, and it is earnestly hoped that replies will be received from a substantial number—why should it not be signed by them all?

As was mentioned in a previous communication, the sum—a very small one when the number of those interested is remembered—of £250 is required to defray the cost of the circular. A certain proportion of this sum has already been received, but our treasurer, Dr. K. Barrett, 102, Church-street, London, S.W.8, will gladly receive and acknowledge further contributions, which are needed.

I am, Sir, yours faithfully,
ERNEST E. WARE.

Welbeck-street, W., Feb. 17th, 1930.

LARYNGEAL PAPILLOMA FOLLOWING GASSING.

To the Editor of THE LANCET.

SIR,—I have been invited to collate papillary granuloma of the larynx, or cases of a similar nature, with a history of exposure to mustard or other irritant gas, for presentation at the summer meeting of the Laryngological Section of the Royal Society of Medicine. The points of note appear to be:—

1. Signs and symptoms, clinical appearances.
2. Date of exposure to gas; nature of latter.
3. Latent period, if any.
4. Operative measures; exact site of granuloma; pathological report.
5. Exclusion of syphilis/tubercle; ? blood or sputum examination.
6. Subsequent history.

I should be very grateful if any of your readers will supply me with notes of cases of this seemingly somewhat rare condition that they have seen. Illustrations, microscopic slides, and (of course) personal presentation of notes at the meeting will be especially welcome. References to published cases, or to occurrence apart from war service, will be valued. Any communication should be addressed to me at the Royal Infirmary, Bristol.

I am, Sir, yours faithfully,
E. WATSON-WILLIAMS.

12, Victoria-square, Clifton, Bristol, Feb. 13th, 1930.

REST IN THE TREATMENT OF GONORRHŒA.

To the Editor of THE LANCET.

SIR,—Dr. Spence's instructive article in your issue of Jan. 4th clearly emphasises the virulency of the gonococcus and the potential mischief of which it is capable. This devastating microbe, of course, invades the male via the meatus, and then enters the anterior urethra, creating intense surface inflammation, but at the same time insinuating itself by division down every microscopic gland of the mucosa. No other microbe is capable of raising such a "bonfire" of inflammation, so that once implanted its presence should, under no circumstances, be deemed of trivial account, lest some of those who have not had occasion intimately to study the habits of this particular microbe should be led into taking a light view of the situation at the only period when one may prevent extension backwards beyond the compressor urethræ.

To accomplish this very desirable result, and even to give a reasonable chance of its being achieved, the patient should be told—just as positively and emphatically as in the case of, say, an acute antrum—that he should go to bed and lie up, and it should be explained to him that without this all-essential element of complete rest, it is quite impossible to hold out the hope of a cure within a reasonable period; still less that he should escape serious complications, even though the newest and most infallible of irrigations be diligently employed. This necessity for rest in bed is even now too little insisted upon, because of the still persisting taboo, disgrace, and secrecy under which all venereal complaints had to be treated in the old days. Nowadays, when thanks to propaganda, leaflets, &c., these same complaints are a subject of ordinary conversation in mixed companies, the onus of refusing to lie up must be put on the unhappy victim of the complaint, and it must be explained to him that his refusal to do so only means that he runs the risk of the many and serious complications which surround the activities of the gonococcus.

By means of real rest, physical and dietetic, half at least of the very serious complications whose treatment is so ably described by Dr. Spence would and could be altogether avoided.

I am, Sir, yours faithfully,
JAMES B. BYLES, M.B. Lond.

St. James's-place, S.W., Jan. 7th, 1930.

Obituary.

JAMIESON BOYD HURRY, M.D. CAMB.

THE name of Dr. J. B. Hurry, who died on Feb. 13th, at the age of 72, has long been familiar to the profession by his books on "vicious circles." He was a man of wide interests, and had a faculty for communicating them to his fellows. The town of Reading, where he practised as a physician, was perhaps the greatest gainer by his enthusiasm and generosity, but as doctor, archæologist, and botanist he formed an important link of many *circuli virtuosi* which spread far beyond his own acquaintance.

DR. J. B. HURRY.

[*Photograph by Elliott & Fry.*

Son of the Rev. Nicholas Hurry, of Liverpool, Jamieson Boyd Hurry was educated successively at Neuchâtel, in Switzerland, the City of London School, St. John's College, Cambridge, and St. Bartholomew's Hospital, London, where he was resident obstetric physician under Matthews Duncan. After qualifying in 1882, he travelled for a year as ship's surgeon, visiting South America, Australia, and India, and thus laid the foundation of an intense love of travel which he was able to gratify in later years by tours in various parts of the world, including North and South America, Egypt, Morocco, and almost every European country. By these means he acquired an interest in continental medical schools, in international social questions, and especially in tropical and economic botany. In 1885 he became partner of the late Mr. George May, of Reading, where a long and active professional life extending over 40 years was spent. During this period he was a keen member of the Reading Pathological Society, and became deeply impressed with the social and professional value of medical societies, in evidence of which he published "A History of the Reading Pathological Society," and afterwards "The Ideals and Organisation of a Medical Society," which has been in wide request by the officers of medical societies at home and abroad. It was not until 1911 that he produced the first of his classical monographs—namely, "Vicious Circles in Disease"—but the idea behind them proved so instructive that it was followed in succession by works on the vicious circle of neurasthenia, sociology, and poverty. The subject aroused keen interest abroad, as was shown by the various foreign translations; the first book appeared in French, Spanish, and Italian, and "Vicious Circles in Poverty" was translated into Chinese. Japanese, French. Spanish, and Italian. These books have undoubtedly done a great deal to draw attention to the importance of the "circular process"—a process which every clinician and every politician must recognise with profit.

At Reading Dr. Hurry became the historian of the Abbey, and took much interest in the preservation of the ruins. During later years he devoted a good deal of time to yet another hobby, economic botany, and established an educational garden at his home at Reading, where were assembled from all parts of the world numerous tropical and economic plants, more especially such as yield food, fibre, dyes, or medicines for the service of man, tender plants being housed in a series of hot-houses. Close by was established a museum in which were exhibited many of the products derived from the plants growing in the garden and conservatories. By this means the plant and its economic product could be studied side by side, and this practical method of studying economic botany attracted large numbers of visitors from far and near. In 1926, owing to impaired health, Dr. Hurry retired from practice and moved with his family to Bournemouth. The collection of tropical and economic plants from Reading was presented to the Corporation of Bournemouth, which has housed them in the King's Park Nurseries at Boscombe. Even in his retirement his pen was never idle, and he published a volume entitled "Imhotep, the Vizier and Physician of King Zoser, and afterwards the Egyptian Deity of Medicine," of which a second enlarged edition appeared in 1928. At the time of his death he was engaged in writing a volume on "Woad," which will shortly be published.

Dr. Hurry married Gertrude, the daughter of Arthur Hill and a niece of Miss Octavia Hill. He leaves a son and a daughter.

ENLARGEMENT OF BECKETT HOSPITAL, BARNSLEY.—Lady Sutherland last week opened a casualty and out-patients' department at this hospital for which the claim is made that it is "the finest in the provinces." The new building, which is of two storeys, and is structurally connected with the hospital, comprises medical and surgical units, dispensary, casualty receiving and dressing rooms, a radiographic unit, massage, ophthalmic, dental, and other departments. The area Miners' Welfare Fund granted £22,000 towards the cost, the Barnsley British Co-operative Society gave £1500 and the X ray apparatus.

HOSPITALS IN EAST AFRICA.—In a debate on Colonial policy in the House of Commons on Dec. 11th, Mr. Marley said that he was informed that there was only one native hospital in the whole of the East African territories. Writing in the *Times* from Nairobi, Dr. James H. Sequeira points out that in Kenya alone there are 18 Government native hospitals with 1371 beds, with 61 dispensaries attached to them, and that five new hospitals will be in commission by the end of the present year. In 1928 21,236 in-patients and 186,545 out-patients were attended in these institutions, and, in addition, 300,000 patients were attended at out stations and by medical officers on tour.

Medical News.

UNIVERSITY OF OXFORD.—On Feb. 15th the following degrees were conferred:—

B.M.—R. S. B. Pearson and J. K. Marshall.

UNIVERSITY OF LONDON.—At a meeting of the Senate on Jan. 29th it was resolved that the subject of the essay or dissertation for the Rogers Prize for 1931 should be Filtrable Viruses as a Cause of Disease in Man.

The University Medal at the M.D. Examination (Branch I, Medicine), December 1929, has been awarded to Cyril Francis Fernando, of University College Hospital.

The Senate will shortly consider applications for grants from the Thomas Smythe Hughes and Beaverbrook medical research fund. Particulars may be had from the Academic Registrar.

The election of Beit Fellows will take place about July 15th, not more than three Fellowships, of £250 per annum, being awarded for scientific research. Information may be had, by letter, from the Rector of the University.

University College.—A course of four lectures on Chemistry of Muscle in Relation to Problems of Cellular Physiology will be given at the College by Prof. Otto Meyerhof, of Heidelberg, at 5.15 P.M., on March 6th, 7th, 10th, and 12th. Prof. A. V. Hill, F.R.S., will take the chair at the first lecture.

MEDICO-LEGAL SOCIETY.—A joint discussion with the West London Medico-Chirurgical Society will be held at 11, Chandos-street, Cavendish-square, W., at 8.30 P.M., on Friday, March 7th. Lord Riddell, President of the Medico-Legal Society, will open a discussion on the Doctor in the Law Courts, and among the speakers will be Sir William Willcox and Dr. F. Temple Grey.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL. Prof. E. B. Verney will deliver the Eighth Biennial Sydney Ringer memorial lecture at this School on Monday, March 17th, at 5 P.M. His subject will be the Reserve Forces of the Kidney.

UNIVERSITY COLLEGE HOSPITAL.—At 3.30 P.M. on Wednesday, March 10th, Prince George will open the new Preliminary Training School for Nurses, which has been presented by the Rockefeller Foundation.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—A meeting of the Council was held on Feb. 13th, with Lord Moynihan, the President, in the chair.

The Honorary Medal of the College was awarded to Prof. Grafton Elliot Smith, F.R.S., in appreciation of his services to the Museum.—Mr. Victor Bonney was re-elected the representative of the College on the Central Midwives Board, and Mr. R. E. Kelly was re-elected a Member of the Court of the University of Liverpool.—Mr. J. Herbert Fisher was appointed Bradshaw Lecturer for the ensuing year.—It was reported that Sir Arthur Keith's Hunterian Lectures would be given on May 5th, 7th, 9th, 12th, 14th, and 16th.

The Fellowship of the College was conferred on Mr. G. C. Dorling, of London Hospital, and the Membership on 135 of the candidates whose names were given in our issue of Feb. 8th (p. 326) as recipients of the L.R.C.P., excepting Rosa E. Chamings, B. S. Cornell, A. N. Duggal, A. H. Gurney, E. Marks, H. P. Nelson, and Alison J. Rae. It was also conferred on C. C. Bryson, Cambridge and Middlesex, and S. Scher, Cape Town and University College.

Diplomas in Public Health were granted jointly with the Royal College of Physicians to the 41 candidates whose names were given on Feb. 8th.

It was announced that the Evening Reception at the College in connexion with the Jubilee celebrations of the Ophthalmological Society of the United Kingdom would be held on April 3rd.

It was reported that Mackenzie Mackinnon Research Fellowships had been awarded to Dr. Thomas Cecil Hunt for research on duodenal catheterisation, and to Dr. George Scott Williamson for research on the study of diseases of thyroid, thymus and lymphatic tissues.

The President stated that an election of three Fellows into the Council would take place on Thursday, July 3rd, at 11 A.M., in the vacancies occasioned by the retirement in rotation of Mr. R. P. Rowlands, Sir Percy Sargent, and Mr. Victor Bonney; that notice of the election would be given to the Fellows by advertisement and by circular on March 7th; that March 17th would be the last day for the nomination of candidates; and that a voting paper would be sent on April 1st to every Fellow of the College whose address is registered at the College.

laid down that a patient must be discharged in any case within 28 days of recovery of volition. What they had tried sincerely to do was to protect the individual and at the same time not to introduce the process that was commonly associated with entering into a mental institution. He believed that this clause would mark a great advance in the treatment of incipient mental disorder, but he was equally sure that the intervention of the magistrate in these cases would destroy the whole value of the clause. If they condemned these people to certification they would not get the early treatment that was desired, and one of the main purposes of the Bill would have been defeated. A large body of public opinion was prepared to support this measure and get rid of what had been called the stigma of judicial interference. He might claim that in this matter they had the vast majority of the medical profession behind them. Lord Dawson had spoken warmly in support of the Bill. It was significant that when, in the House of Lords, an effort was made to introduce intervention of the magistrates, two of the law lords opposed that view and supported the Bill. Other clauses dealt with provisions regarding local authorities. Their powers and duties were enlarged and they were enabled to do more in the way of facilities for treatment. They were also given power to provide out-patients clinics, to undertake after-care, and to undertake research. These powers were subject to the approval of the Board of Control and were so drawn on the specific recommendation of the Royal Commission. Objection had been taken to making this a new duty, but it was not so much a new duty as the application of an old duty in a different way. If they modified the law with regard to local authorities, they ought to modify the law with regard to the central authority, and the whole point of the reorganisation clauses was to re-establish the Board of Control on a new basis, with a closer contact with the local authorities and with the procedure and method of administration assimilated to that which was followed now in the Ministry of Health itself. The whole desire behind these proposed alterations in the Board of Control was to adapt that central machinery to the rapidly developing work within the sphere of the Board. It had been stated that the Board of Control was a Star Chamber which was not within the jurisdiction of the House, but nothing could be more untrue. Parliament would have the final say in the matter of the detailed administrative rules. The Royal Commission desired a complete overhaul of the lunacy administration. That had not been possible, but it had been possible to dissociate people suffering from mental disease from the poor-law.

The Practitioner's Peril.

The remaining clauses of the Bill dealt with one or two matters of importance. Clause 16 referred to the protection of medical practitioners who gave certificates under the Lunacy Acts. The position of the medical practitioner to-day was one of considerable uncertainty, indeed many of them thought it one of very real peril. The Royal Commission recognised it. To-day, if the medical practitioner was made defendant in a case for wrongful certification, the onus of proof rested upon him to show that he had acted in good faith and with reasonable care. He (Mr. **GREENWOOD**) thought it was clear that they could not completely remove responsibility from the medical man. After all, he had made a decision and, therefore, while they must keep upon him a certain measure of responsibility, it was important on the other hand that he should have reasonable protection against cases which might be brought, and which might mean his financial or professional ruin, even if the cases did not go against him. The clause in the Bill followed very closely the proposal made in the Royal Commission's report which was drafted in detail by the very eminent legal members of the Commission. As regarded the proposals of the Royal Commission about the assimilation of procedure, he thought it would have been admirable if it could have been done. But he was not sure that it could have been done very simply. On the other hand he was quite clear that it would make the Bill highly controversial, and his aim was to get a minimum of controversy in regard to the measure. It would also, perhaps, have been advisable to follow the report of the Royal Commission in regard to the licensed houses, but that too was a burning of the full of deep-seated differences of opinion. These matters, therefore, had been deliberately excluded from a Bill which was designed to meet an urgent need and to revolutionise the public mind in its attitude towards mental disease, and to provide early treatment for that disease. It was also designed to reorganise the administrative machinery so as to make the constructive proposals more nearly operative and more successful. He thought that the House would not find in the Bill any cause for blind difference of opinion. He hoped that the second reading would be carried so that it could go to a Standing Committee. In committee, every effort would be made to accept amendments which would really improve the measure, provided that they did not interfere with the principles on which it was based.

A Saner View of Insanity.

Sir **KINGSLEY WOOD** said that he welcomed the main provisions of the measure because he thought it represented a saner view of insanity. Provided that opportunities were given for the discussion of certain points, the Opposition hoped to be able to coöperate with the Government in the passage of the Bill. Speaking subject to what might be said by the medical Members of the House, he thought it might be said that mental illness was not being reduced in this country. The recovery-rate was not a particularly good one. There was an increasing number of persons suffering from temporary mental troubles due to the increasing speed and strain of life. He was glad to think that in many respects the old conceptions and unhappy methods concerning mental illness were disappearing, but they died hard. They were still in many respects manufacturing lunatics; the old idea of the hopelessness and helplessness of mental disease still prevailed in many quarters. There was still the stigma of lunacy harking back, no doubt, to the time when madmen were kept in chains and underground cellars. He thought that there were two grave defects in the present system. The first was that the present law undoubtedly placed many obstacles in the way of early diagnosis and early treatment; and secondly under present circumstances and the present law there was very little hope of recovery for many poor people in this country. The poorer patient must have reached the final stage before a mental hospital could receive him. He welcomed the proposals in the Bill with regard to what was called the voluntary boarder. He suggested that it might be possible to remove this class of patient altogether from the jurisdiction of the Board of Control, and by that means dissociate this kind of illness from lunacy. That might very well be discussed in committee. A good deal of importance was attached by eminent lawyers in the House of Lords to the fact that inasmuch as minors could be detained in homes of that character for a certain period at the request of parents, the Board of Control would cause the homes to be visited by commissioners, as some measure of protection. How far that protection was substantial could no doubt be considered when the Bill was in committee.

In Clause 5 provision was made for treatment without certification of persons "temporarily incapable of volition." That was a matter which ought to be carefully considered, to see whether every protection was afforded. For the first time an order was to be signed without what was called a judicial authority. If it were possible, subject to proper safeguards, to avoid certification, it ought to be done. Certification as a lunatic raised real apprehension and dread in the minds of large numbers: once a person has been so certified, even if he or she recovered, it followed them for the rest of their lives. He doubted, however, whether, from the point of view of the liberty of the subject, the intervention of a Justice of the Peace was any protection. The Justice of the Peace who did his duty seriously in that connexion would be in a most difficult position if he were confronted with certificates signed by competent medical men. If regard were had to the reports of the last two tribunals which have been set up by the House to consider the treatment of lunacy, cases of wrongful detention must be of the rarest occurrence, and ill-usage was not deliberately or systematically practised in the institutions. He placed a great deal of confidence in the Board of Control and its operations, and the fact that members of the Board could visit those institutions at any time was a considerable safeguard. He hoped that one result of the measure would be that the superintendents of those institutions would have more time to attend to their proper job and would be relieved of many duties which did not apply properly to them.

The provisions of the Bill which called for further consideration were those relating to the medical profession of the local authorities. He had a good deal of sympathy with the plea of many medical men that some further protection should be afforded them in the discharge of their duties under the Bill than its provisions provided. Additional responsibilities were placed on local authorities, and he had been asked by the London County Council to put forward on their behalf and on behalf of other local authorities, a claim for further financial assistance. The Bill was on the right lines, and the Opposition would be happy to assist in its passage.

"Voluntary Patients."

Dr. **MORRIS-JONES** said that 20 years' experience as a medical practitioner had convinced him more and more that there was a very urgent need for such a measure as this Bill. Mental disease in recent years had become more and more allied to physical disease, and after all the line of demarcation between the two was very thin. He welcomed Clauses 1 to 4 dealing with voluntary boarders. He would prefer the term "voluntary patients." He also welcomed Clause 5 which dealt with persons incapable of volition. It was, in his opinion, the crux of the measure and had been considerably improved during the passage of the Bill through the House of Lords. It was reassuring to be told by the Minister of Health that he would be responsible for the Board of Control on all occasions. He would like to see a little more protection for the medical profession than that given in Clause 16.

Dr. **ETHEL BENTHAM** said she heartily welcomed this Bill which was a step in the beginning of a reform which had been overdue for many years. She had had 13 years' experience as a general practitioner, and had acted as a magistrate ever since women magistrates were first appointed, so that she had had considerable knowledge of this question. When in the interests of a patient she had had to go to the Board of Control she had found it human—when one could get at it. The mental patient needed to be protected, first of all against himself, and in many instances against his relatives; in her experience the relatives were the people from whom he most often needed to be protected. If it was laid down that in every case, pauper or otherwise, two medical opinions had to be obtained, then in her opinion a certificate of a justice of the peace was not much needed. The non-medical justice was at such a disadvantage in face of medical certificates that it was really better to have the opinion of two medical men. The re-christening of the Board of Control would be quite useful, but some steps must be taken to give an appeal to the Board and to bring about greater public confidence in that body. She thought that the number of three members was too limited. It would be necessary to have two doctors—one a man and the other a woman—on the Board, and she thought the membership should be enlarged to five.

A Supervisory Authority.

Dr. **SOMERVILLE HASTINGS** said that all who were interested in the early treatment of mental disease would welcome the Bill. There might be two opinions as to the exact status of the Board of Control, but such matters might very well be dealt with during the committee stage of the Bill. He would like to add to the list of the Board's functions a supervisory function in connexion with the treatment of cases suffering from mental disease. That function was a very right one. It might be necessary to alter the exact status of the Board of Control, but he felt very strongly that some supervisory authority would always be necessary in dealing with mental disease. There were two considerations in connexion with mental disease which required attention. The first was the question of what was best for the patient; what treatment ought to be given, and what could be done to increase the patient's comfort. Another important point was the protection of the public, the protection of the patient from himself, and the protection of the good name of the patient's family. To achieve this latter object some form of detention was necessary. He was associated with a hospital which treated early cases of mental disease, and their difficulty was that they had no power of detention at all. Therefore, their selection of cases was strictly limited, and they could not forcibly detain patients even when it was in their own interest and when they felt that they ought to be detained. He wished to lay stress more particularly on the possibility of the treatment and cure of mental disease. Not long ago mental disease was thought to be an act of God, but now they were learning more and more that something could be done to alleviate this disease, and sometimes to cure it. He had seen cases of severe insanity treated and cured by ordinary medical treatment, or by a relatively simple operation on the nose. Many of the patients at his hospital suffered from some other medical or surgical ailment that could be recognised when the patients were closely examined by physicians and surgeons accustomed to deal with those other affections and when those other conditions were treated the patients very often rapidly recovered. One great point in favour of this Bill was that it would allow public money to be spent on the treatment of early cases of mental disease which was now impossible.

There was a type of patient not dealt with in the Bill, but about whom it was important to say a word or two—the patient who did not know that he was insane, but thought everybody else was. These were the people whom it was desirable to consider at present. Sometimes they recovered, as had been shown by the Minister of Health, but when they ceased their anti-social behaviour their ego did not change. They did not believe that they were insane before, and when they recovered they did not believe that they had been insane. These were the people who wrote pamphlets and distributed them to Members of Parliament and tried to catch Members of Parliament in the outer lobby of the House. It was these people who tried to impress the public with the evils of asylum treatment and with the sins of the Board of Control. They had to recognise that a great many early cases of mental disease were curable, but it was necessary to have some power of detention in such cases and unless that power was obtained, not very much could be done. He was very interested to hear the Minister of Health say that the stigma of certification was a real thing. There was no question that that was the case, and the stigma of association with the certified was also a real thing. He would like to see further provisions in the Bill for the withdrawal of the voluntary boarders and those not capable of volition, as far as possible from association with the certified, and for bringing them into closer association with the treatment of ordinary medical and surgical diseases. If a clause could be inserted in the Bill encouraging the local authorities, or even compelling them to do this, it would be a very great help. Although there might be ways in which the Bill could be improved in the Committee, it made a very great advance in providing for the treatment of early mental disease.

The Bill Supported.

Captain **GUNSTON** congratulated the Minister of Health on introducing the Bill, which, he said, he wished had been more far-reaching. They ought to be grateful for the name of the Bill—"The Mental Treatment Bill,"—because it described so exactly what they were trying to do. There was some misconception in the country as to the difference between a mental deficient and a person mentally affected. The Bill did not deal with the mental deficient. Everyone would congratulate the Government on bringing in a measure which would enable the poor to get very early treatment and, in many cases, to be cured.

Mr. **LOGAN**, speaking as one who had had some experience of poor-law administration, supported the Bill. The passing of the old boards of guardians, and the coming of the Public Assistance Committees was bringing in a new trend of thought and a new system into the management of the affairs of the nation. The Minister of Health should take into consideration the question of segregation. It was utterly impossible to deal with mental cases, whether certifiable or for temporary treatment, unless they were segregated. Without segregation, classification would be useless. Both were absolutely essential. Provision should also be made for classification of cases of senile decay, in addition to classification of temporary cases which were not chronic.

Mr. **R. RUSSELL**, in supporting the Bill, said that in Committee the whole question of the relationship between the local authorities and the Board of Control would come under very serious consideration, and would need some remodelling. The local authorities had built up these great institutions and had done magnificent work, but they were very much alarmed at the powers which were given to the Board of Control in regard to them. There was no doubt, also, that considerably increased expenditure would be placed upon the local authorities.

Dr. **FORGAN** said that he gladly joined in the chorus of praise of the Bill, though he would have to qualify it to some extent by calling attention to one or two defects. He would like to say what great benefit institutional treatment for voluntary boarders and the possibility of after-care treatment could be. The Bill did not apply to Scotland, for the very good reason that Scotland had its separate Board of Control, and a member of the Royal Commission had stated that the practice in Scotland showed an enormous advance upon that in England. In Scotland, those suffering from mental disorder were treated in a very flexible way, with enormously good results from the point of view of the health of the patient. The percentage of the population certified as insane was almost 20 lower than in England, and the different method of treatment might to some extent be responsible for that. He had had brought to his notice some time ago the case of a young man who had been unemployed for a considerable time, and fear of future unemployment became such an obsession that finally he had to be admitted to a poor-law institution where, after some months of doubt, not as a certified lunatic but as a voluntary boarder, he was restored to normal mental health and discharged. Then he had to face again the very trouble that had driven him into the mental institution—the fear of continued unemployment. It was only necessary to draw the attention of the local authority to the fact that he was up against the thing that had practically made him insane before, for the parish council to provide him with work. By means, first of all, of treatment, and afterwards by after-care, he was saved from what certainly would have been permanent insanity. He commended to the notice of the House the practice in Scotland, which apparently was considerably in advance of that in the South. As regarded the defects in the Bill, temporary patients were, in the opinion of those who had framed the measure, likely to be treated in the existing poor-law institutions, and many members of the public would think there was very little difference between a declaration signed by two doctors and certification, if the patient was then removed to an asylum. That emphasised the paramount importance of setting up other institutions for the treatment of early cases. But the most important defect was the very serious additional financial burdens which would be placed on local authorities. Temporary patients were an entirely new class of patient. Fresh accommodation would be required for them, and fresh expense would be incurred by the authorities and, if the method of allowing non-volitional cases to remain for six months without certification was going to be effective at all, it would mean for some years an increase in the number of persons who would receive treatment and new accommodation would be required if the authorities were to put into effect the permissive powers which the Bill gave them. The Royal Commission declared that the Exchequer contributions to local authorities for work of this sort in the past were wholly inadequate, and they themselves were of opinion that an ad hoc grant was necessary if local authorities were to undertake the new duties. Local authorities were now faced with additional work, with their resources for further rating depleted by the De-Rating Act of the last Government. He was afraid, if this subsection was to remain permissive, that the great majority of the local authorities would be unable financially to undertake any work at all. The Bill, as it stood now, was not going to provide early treatment except for those who were able to pay for it. The history of lunacy reform had been a history of good intentions. In 1881, the Commissioners reported that for 40 years their efforts had been directed towards obtaining early treatment. That was 39 years ago, so that for almost 80 years the Commissioners had been attempting to obtain early treatment. Early treatment was the keynote of this Bill. He hoped that the Bill would have a unanimous second reading, and that at a later stage it would be so amended as to make it really capable of bringing about a praiseworthy reform.

Sir JOHN WITHERS, speaking as one who had had a good deal of experience in lunacy work, said that on the whole the Bill was extremely good. Clauses 1 to 4 were excellent, but he must refer to Clause 5. He had an old-fashioned dislike to doing away with the certificate of the magistrate. That had been, on the whole, a great safeguard. Under this Bill people could be put away in an asylum or home for a whole year without any legal certificate, and his feeling was that that was a mistake. He could see no reason for it. The idea that certification of itself was a stigma was a misconception. From the point of view of the patients themselves, certification was a protection. It protected the patient, the doctors, and the family. The expression "incapable of volition" would also have to be explained, and there ought to be some mode of appeal from the Board of Control.

Non-volitional Cases.

Lieut.-Colonel FREMANTLE said that they were dealing with the distressing cases which numbered already some 135,000 persons in mental institutions. Of these, it was estimated that about one-third were what were called in the Bill non-volitional cases. That was to say, from 40,000 to 50,000 were non-volitional cases. As had been said, the expense and necessity of providing for these people was already met. Therefore the need of new accommodation did not arise in their case, although one naturally hoped that, in time, better accommodation might be provided for them as for others. With regard to the non-volitional cases, one of the objects of the Bill was to lead those who at present were frightened off from certification to submit themselves to treatment, or to be submitted by those responsible for them. Therefore there would be need of further accommodation. It was well for them to recognise that there had been some exaggerated enthusiasm about the Bill as opening a new era. The treatment of the insane had varied with the conception and knowledge of their condition. Although the way of representing insanity of older times had gone out of fashion, he was doubtful whether the modern jargon of psychology which had taken its place gave any more accurate and scientific picture than the old idea that an insane man was possessed by a personal and malign influence. The idea of a man "possessed of a devil" gave way to the idea that an insane person was divinely afflicted and had to be restrained as a danger to society and to himself. The first organic stage in our system for dealing with lunacy might be said to have started with the Elizabethan poor-law and the institutional arrangements which arose at that time. The process of dealing with the insane then was one of mechanical restraint, and that idea continued until King George III., who was himself a sufferer, was treated under humane conditions by Dr. Addington, a physician of that day, and father of the statesman, Lord Sidmouth. He introduced the idea of humane treatment which, applied in such an exalted sphere, naturally attracted attention. Still, the idea of mechanical restraint held sway in the beginning of the last century, until Charles Reade wrote "Hard Cash," and Cockton wrote "Valentine Vox." The indignation aroused was such that finally the lunacy laws were amended. The great Lord Shaftesbury was responsible more than anyone else for the passing of the 1845 Act, known as the Magna Charta of the insane, and he became one of the first Commissioners in Lunacy. He was so much averse from the introduction of the justice into the business of certification of the insane that when, eventually, the Act was passed, he resigned his Commissionership in protest, and stood for the principle which was being introduced in the Bill that day. From that time onwards they had had a conflict or clash between what had been called the static mind of the lawyer on the one hand, and the dynamic force of the biologist on the other—that clash which was described by Prof. Kenny in his "Outline of Criminal Law." It was no disparagement to the legal profession to refer to the static mind of the lawyer, because the law must necessarily deal with concrete and defined facts, and that really created the difficulty in this case.

The Doctor's Viewpoint.

The medical profession had necessarily to look at it from the other side. He spoke, not as one who had practised the profession of curative medicine, but from the administrative point of view, the view of the lay authority and of the interests of the community as a whole, and especially from the point of view of prevention as well as of cure. Therefore he again called attention to the position of the medical man in the case. It had been referred to already so pathetically and intimately by his professional colleagues who had spoken in the debate, but he asked the House to consider the position they were in when called on to deal with a case that was first of all recognised in a family as one of difficulty, of violent temper, of a rather changeable and fickle state of mind, of a person difficult to deal with. Commonly, the person was regarded as not only a nuisance, but as being voluntarily responsible for the trouble in the family and the household. The medical man came in and realised that it was a case where the strain, in one form or another, had been so great as temporarily to derange the mind of the individual. It was a temporary early case, and it would be ridiculous to sign that as a case of certified insanity. It was obvious, from the mere facts of the case, that it arose from the normal incidents of health and ill-health in a life; such cases as arose after childbirth, after fevers, confusional cases, and temporary alcoholic or toxic cases. These were difficult cases that arose and which had to be treated by the medical man, who said "It is absurd that this should be signed up as insane." These were the cases which up and down the land at present were not being certified and never would be certified. Therefore, here was a way in which these people could get the expert care, comfort, and treatment that would enable them to tide over the time until they could again resume their normal place in family and public life. It must invite the sympathy of everybody who understood the case. When the doctor was called in the case might be in a violent temporary state of insanity. What was the doctor to do? He chafed at delay, and the relatives chafed at delay, but as the case was at present the only possibility for these violent cases was to search out a justice of the peace. He spoke as a justice of the peace as well as a medical man, and he knew how difficult it was for individuals to find a justice of the peace when he was required in such a case, or to find one who was able to go into the case. As had been well said already, as a rule the justice of the peace deferred to the medical man's opinion, and said "the medical man says so, and obviously I must sign it up." It was true, as the Royal Commission found, that the safeguard of a justice of the peace having to certify a case was a very small one compared with the safeguards provided in this Bill. They had a man who, it seemed to him, was more qualified to look after the safety of those concerned than a justice of the peace, because he was to be a medical man approved by the Board of Control. In fact the criticism of this proposal made from the medical profession was that it might start a new specialty—a separate and distinct class of practitioners. Be that as it might, he thought that the Board of Control would obviously approve only men who would take public point of view, and who would realise their responsibilities in the matter. He wanted the House to sympathise with the ordinary family doctor and help him to get through these delays and difficulties that were so troublesome and tiresome to the patients and their families. The medical man realised equally well the necessity for protecting the personal liberty of the subject. He did not believe that anybody so much as the medical man would be so acute and keen to discover any kind of ill-treatment and mischief that was going on in a case. Till the end of time there would always be cases where the law would be defeated; no law would be perfect, and those who supported this measure so keenly only asked people to recognise that they had put in a safeguard of a medical man approved by the Board of Control in addition to the family doctor as a more efficient person than the judicial authority. In regard to the Board of Control he (Colonel Fremantle) agreed with many of the criticisms.

It had been suggested that there was a stigma attached to the Board of Control, and that a new body should be formed to deal with these persons. There was no need to have a fresh Board for every class of insane or mentally afflicted persons who were to be treated.

It was in order to get rid of the stigma that the Mental Deficiency Bill of 1913 was passed, and that the Lunacy Commission was absorbed in the Board of Control. Some stigma must attach to any body that undertook these functions, because they were concerned with people who might eventually be certified as insane. They must trust the Board of Control, and in committee they could consider the clauses dealing with the Board in order to secure that the Board would have the confidence of the public as being efficient and expert, and at the same time a sensible body to deal with this subject. But unless they gave a salary and position to the Commissioners greater than those already enjoyed by the class of experts from whom the Commissioners were drawn, they would not get the right class of experts to give their services, and who would command the respect of the superintendents of the institutions engaged in the treatment of mental disease. Sir Maurice Craig, in his evidence to the Royal Commission, said that he had seen in the Board of Control a considerable change and progress in methods; his former criticism had passed away, and he believed that there was evidence that they were doing their work well and in a progressive manner. The House must not forget the matters which were naturally left out of the Bill, and which appeared in the Royal Commission's report. There were two germane matters which did appear in the Bill, which were of immense importance to the treatment of the individual before and after treatment institutions. Those were the systems of after-care and medical hygiene generally. There were many associations which undertook this voluntary work, which was invaluable. Some power was given for after-care, and in committee they would want to extend the powers given to after-care associations in various ways, because everybody would realise that the real trouble of the temporarily insane person began when he got back to his own home, especially in the poorer homes. These people then met all the weight of domestic responsibility and domestic trouble and inconvenience, and had to fend for themselves. The whole of the good done by six months' or a year's rest in an institution might be dissipated in three months if there was not sufficient after-care. Above all, they must remember that they wanted to be able to treat cases as early as possible, with a view to preventing many of the 50,000 people who were now in mental institutions from having to undergo institutional treatment. With newer ideas and newer possibilities they hoped to get them early and develop the prevention, rather than have to engage in the cure of the hopelessly insane.

(To be continued.)

HOUSE OF COMMONS.

WEDNESDAY, FEB. 12TH.

Lunatics and Cottage Homes.

Major GLYN asked the Minister of Health whether, before his department agreed to the maintenance of lunatics in cottage homes in rural areas, he would ascertain the opinions of the county councils, in view of the effect such a proposal would have in many villages.—Mr. GREENWOOD replied: All relevant considerations will, of course, be borne in mind before effect is given to any proposals of this nature.

Notification of Cancer.

Major GLYN asked the Minister of Health whether, on account of the public concern and uncertainty regarding the cause and effect of cancer, he would consider having this disease made notifiable, thus enabling the Cancer Research Council to obtain extra data and assisting local practitioners to obtain specialist advice in the earliest stages of treatment. —Mr. GREENWOOD replied: I do not think that compulsory notification of cancer, which would probably entail legislation, would be effective in securing early diagnosis, which I am advised is the first essential.

THURSDAY, FEB. 13TH.

Death from Anthrax.

Mr. JOWETT asked the Home Secretary whether his attention had been called to the death from anthrax of Mrs. Lily Kalaher, who had been employed as a woolsorter by Messrs. William Root, Limited, of Bradford, and to the evidence given by Dr. Eurich, bacteriologist, at the inquest to the effect that the grey Syrian wool that she had been sorting ought to be scheduled as dangerous, and that the disinfectant used as a precaution against anthrax at the mill was useless; and, if so, whether he intended to schedule grey Syrian wool as a dangerous wool without further delay. —Mr. CLYNES replied: I have received a report on this case by the factory inspector who attended the inquest. This shows that Dr. Eurich gave evidence to the effect suggested in the question, but it also appears that previous to the onset of the disease the unfortunate woman had been sorting other material besides grey Syrian wool, and the precise origin of the infection does not seem to have been established at the inquest. The question of an extension of the Wool Sorting Regulations deserves and will receive prompt and serious consideration, but it will be necessary, before any decision is reached, to make further inquiries and review the position in the light of all the information available. I may add that the inspector reports that the requirements of the Regulations were fully observed by this firm, and were applied not only to scheduled but also to non-scheduled wools, so that even if grey Syrian wool had been scheduled, it would not, apparently, have made any difference in this case.

Diagnosis and Treatment of Silicosis.

Mr. HOFFMAN asked the Home Secretary whether in the legislation he proposed to introduce setting up medical boards for the purposes of the diagnosis and treatment of silicosis, for research purposes and training, the central bureau is to be in Sheffield; and when it was proposed to introduce such legislation.—Mr. CLYNES replied: Yes, Sir, it is contemplated that the centre of the new organisation which would be set up for the purposes of the medical examinations required under the Act, should be at Sheffield. I regret I am not in a position to say when the proposed Bill will be introduced.

Psittacosis.

Sir GEORGE BOWYER asked the Minister of Health: (1) whether he would adopt the suggestion made by Lord Dawson, that an embargo be placed upon the importation of all parrots for a reasonable period, in view of the danger of a spread of parrot disease; and (2) whether he had received notice of the warning of an epidemic of parrot disease which was given last week by the doctor at the inquest on Miss Rogers, who died from psittacosis; and what steps the Ministry of Health were taking to assist in the diagnosis and treatment of this disease.—Mr. GREENWOOD replied: I have seen a newspaper report of the inquest on this case. The steps which have been and are being taken by my department in this matter are summarised in a memorandum which has recently been issued to local authorities and is now on sale. The question whether it is desirable to place any restrictions on the importation of parrots is under consideration, but I am not at present satisfied that such measures are necessary for the protection of the public health.

Dietary and Dental Decay.

Lieut.-Colonel FREMANTLE asked the Minister of Health whether his attention had been drawn to the researches at Sheffield University, now being published by the Medical Research Council, into the effect of a proper dietary for expectant others and for children in the prevention of dental decay; and whether he would issue to maternity and child welfare centres a paper of simple information and guidance for those attending such centres.—Mr. GREENWOOD replied: The answer to the first part of the question is in the affirmative. As regards the second part, it is the common practice at these centres to give advice as to a correct dietary, including instruction with a view to the prevention of dental decay, and as at present advised I do not consider it necessary to issue any special paper on this subject.

Dogs and Vivisection Experiments.

Mr. FREEMAN asked the Home Secretary whether any experiments by vivisection were conducted or allowed with the object of benefiting dogs; and, if so, how many were performed last year.—Mr. CLYNES replied: Such experiments would be allowed in suitable cases. During 1929, 451 experiments (all inoculations), of which 74 were on dogs, were performed with the object of discovering a prophylactic serum for distemper. No doubt other of the experiments performed were done with the direct or indirect object of benefiting dogs, but the information in my possession does not enable me to distinguish them with any certainty.

MONDAY, FEB. 17TH.

Pasteurised Milk and Tubercle Germs.

Mr. LAWTHER asked the Minister of Health if any examinations of samples of pasteurised milk by any public authorities had shown evidence of living germs of tuberculosis?—Mr. GREENWOOD replied: I understand that some samples of milk alleged to have been pasteurised have been found by local authorities to contain tubercle bacillus.

Mr. LAWTHER asked the Minister of Health if any examinations which had been made of tuberculous material showed the presence of bovine tubercle bacillus in children who had been brought up entirely on pasteurised milk?—Mr. GREENWOOD replied: I am not aware of any examinations which have shown the presence of bovine tubercle bacillus in such children.

Certified and Grade A Milk and Tuberculosis.

Mr. Lawther asked the Minister of Health what examinations, if any, had been taken of samples of certified and T.T. (Grade A) milks by public authorities; and if such samples had shown any evidence of living germs of tuberculosis?—Mr. Greenwood replied: These milks are not examined for tubercle bacillus as a matter of routine, and I cannot say how many samples have been so examined. I have reports of a few instances in which tubercle bacillus has been found in the milks.

Punishment by the "Cat."

Dr. Hastings asked the Home Secretary in how many cases, if any, during the last five years the administration of punishment by the cat had taken place in two or more stages?—Mr. Clynes replied: In no case within the memory of present officers of the prison service has the administration of corporal punishment taken place in two or more stages. If the medical officer stops a flogging on medical grounds that is final, and the flogging is never resumed at a later date.

Humane Slaughter of Animals.

Lieut.-Colonel Moore asked the Minister of Health the total number of local authorities in England and Wales who had adopted the Ministry's model bye-law 9b in regard to the humane slaughter of animals up to Jan. 31st?—Miss S. Lawrence (Parliamentary Secretary to the Ministry of Health) replied: The number is 349.

Hygienic Methods of Handling Fish.

Mr. Arthur Michael Samuel asked the Minister of Agriculture whether he was framing suitable regulations, to be enforced by law, to ensure more hygienic methods at sea for handling and packing trawled fish, so as to retard what was technically known as autolysis, and to reduce contamination by bacterial infection?—Mr. Buxton replied: Although the report on the handling and stowage of white fish at sea was only published by the Department of Scientific and Industrial Research very recently, steps are already being taken by some owners to equip their vessels with the apparatus necessary for carrying out its recommendations. It is not yet clear to what extent the recommendations can be adopted in commercial practice, but I am confident that legislation will not be required to induce trawler owners and fishermen to take advantage, to the limit of practicability, of the information furnished by the report.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, Feb. 24th.—8 P.M., Odontology. Paper: Dr. Georges Villain (Paris): The Problem of Stabilisation and Articulation of Dentures.

Tuesday.—5 P.M., Medicine. Discussion on The Treatment of Lung Abscess. Openers: Dr. F. G. Chandler and Mr. A. Tudor Edwards. Followed by Dr. L. S. T. Burrell and Mr. J. E. H. Roberts.

Wednesday.—5 P.M., Comparative Medicine. Discussion on Canine Distemper. Openers: Mr. Thomas Dalling and Mr. George W. Dunkin. Other speakers will also take part.

Thursday.—Urology. Meeting at Liverpool at the invitation of the Liverpool Medical Institution. 8.30 A.M. Train from Euston (breakfast train). 12.35 P.M. Arrive Liverpool. Lunch at University Club (opposite Adelphi Hotel). Operations at four Liverpool Hospitals. 3.45 P.M. Clinical Pathological Meeting at the Liverpool Medical Institution. 5.20 P.M. Return train from Liverpool. 9.5 P.M. Arrive Euston.

Friday.—5.30 P.M., Disease in Children. (Cases at 4.30 P.M.) 8 P.M., Epidemiology. Paper: Sir Leonard Rogers: Further Experience in Forecasting Epidemics in India and their Bearing on the Reduction of Cholera Epidemics.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, Feb. 24th.—8.30 P.M., Discussion on the Treatment of Syphilis, to be introduced by Colonel L. W. Harrison.

Wednesday.—9 P.M., Sir John Thomson-Walker: Enlarged Prostate and Prostatectomy (Second Lettsomian Lecture).

ROYAL INSTITUTION, Albemarle-street, W.

Thursday, Feb. 27th.—5.15 P.M., Mr. J. B. S. Haldane: Some Problems of Genetics.

MEDICO-LEGAL SOCIETY, 11, Chandos-street, Cavendish-square, W.

Thursday, Feb. 27th.—8.30 P.M., Lieut.-Colonel Henry Smith: The Forging of Seals and Finger Prints and its Remedy. With demonstrations.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.

Friday, Feb. 28th.—8.30 P.M. Papers will be read by Dr. S. H. Browning and Mr. P. G. Doyne on Syphilitic Diseases of the Eye. A Discussion will follow.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

Thursday, Feb. 27th.—5 P.M., Dr. J. A. Glover: The Incidence of Rheumatic Diseases. (First Milroy Lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, Feb. 24th, to Saturday, March 1st.—Medical Society Lecture Room, 11, Chandos-street, Cavendish-square, W., Tues., at 4 P.M., Lecture by Prof. Dame Louise McIlroy: Lantern Demonstration of the Management of Abnormal Labour. No fee.—All Saints Hospital, Vauxhall Bridge-road, S.W. Wed., 2 P.M., Clinical demonstration, Mr. R. Coyte: Cystoscopies. No fee.—Infants Hospital, Vincent-square, S.W. Fri., 4 P.M., Demonstration, Dr. Eric Pritchard: Difficult Cases of Feeding. No fee.—Children's Clinic and Other Hospitals, Post-graduate Course in Diseases of Children, Afternoon and some mornings. Two weeks.—Royal Eye Hospital, St. George's-circus, S.E. Series of demonstrations on the Diagnosis and Treatment of Diseases of the Eye. *Mon. to Fri., for two weeks daily.—Hospital for Tropical* Diseases, Gordon-street, W.C. Clinical demonstrations, Tues. and Thurs. afternoons at 2 P.M.—Further particulars from the Fellowship of Medicine.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark Hill, S.E.

Thursday, Feb. 27th.—9 P.M., Dr. Sydney Thomson: Ringworm.

NATIONAL HOSPITAL POST-GRADUATE COURSE, Queen-square, W.C.

Monday, Feb. 24th.—12 noon, Dr. Greenfield: Pathology of Nervous System. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Mr. Leslie Paton: Control of Ocular Movements.

Tuesday.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Central Disorders of Vision.

Thursday.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Mr. Just: Deafness in Relation to Intracranial Disease.

Friday.—12 noon, Dr. Purdon Martin: Anatomy and Physiology of Nervous System. 2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Mr. Elmquist: Demonstration of Re-educative Exercises.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, Feb. 24th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

Tuesday.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

Wednesday.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

Thursday.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat, and Ear Clinics. *Operations.*

Friday.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases. Clinics. Operations.

ROYAL NORTHERN HOSPITAL, Holloway.

Wednesday, Feb. 26th.—3.15 P.M. (at the Royal Chest Hospital). Dr. F. E. Saxby Willis: Diaphragmatic Hernia.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

Friday, Feb. 28th.—4 P.M., Mr. F. Walkyn-Thomas: Intrinsic Carcinoma of the Larynx.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

Tuesday, Feb. 25th.—5 P.M., Dr. G. B. Dowling: Seborrhœa. Seborrhœic Dermatitis.

Thursday.—5 P.M., Dr. K. Sibley: Electrotherapeutics.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

Wednesday, Feb. 26th.—4 P.M., Mr. V. Zachary Cope: Demonstration of Surgical Cases.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Keppel-street, W.C.

Thursday, Feb. 27th.—5 P.M., Dr. W. G. Savage: Food Poisoning. The lecture is open to the public.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY, 49, Leicester-square W.C

Wednesday, Feb. 26th.—4.15 P.M., Clinical Cases. 5 P.M., Dr. Kenneth Wills: The Infectivity of the Seborrhœic Organism.

ST. MARY'S HOSPITALS, Manchester.

Friday, Feb. 28th.—4.15 P.M. (at the Whitworth-street West Branch), Dr. J. Crighton Bramwell: Cardiac Complications of Pregnancy. (Post-graduate Lecture.)

ANCOATS HOSPITAL POST-GRADUATE COURSE, Mill-street, Manchester.

Thursday, Feb. 27th.—4.15 P.M., Mr. E. E. Hughes: Renal Tuberculosis.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

Friday, Feb. 28th.—3.30 P.M. (at the Royal Infirmary), Dr. R. Platt: Applied Physiology in the Diagnosis and Treatment of Renal Disease.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

Wednesday, Feb. 26th.—4.15 P.M. (at the Western Infirmary), Mr. J. Mill Renton: Surgical Cases.

Appointments.

Pinto-Leite, H., L.R.C.P. Lond., M.R.C.S., has been appointed Medical Superintendent to the Hospital of S.S. John and Elizabeth, Grove End-road, N.W.

Semple, A., M.B., Ch.B. Glasg., D.P.H., Medical Officer of Health, Carlisle.

Stirling, T. S., M.B., Ch.B. Glasg., D.P.H. Camb., Assistant County Medical Officer of Health for Somerset.

St. John's Hospital, Lewisham: **Gibbens, J. H.**, M.A., M.R.C.P. Lond., M.R.C.S., Physician in Charge of the Children's Department; **Yeo, K. J.**, M.B., B.Chir. Camb., D.M.R.E., Physician in Charge of X Ray Department; and **Brockman, E. P.**, M.Chir. Camb., F.R.C.S. Eng., Surgeon in Charge of Orthopædic Department.

Vacancies.

For further information refer to the advertisement columns.

Ashford Hospital, Kent.—H.S. £160.

Ashton-under-Lyne District Infirmary.—H.S. At rate of £150.

Barrow-in-Furness, North Lonsdale Hospital.—H.S.'s £150.

Bath, Royal United Hospital.—H.S. At rate of £150.

Birkenhead General Hospital.—Sen. H.S. and H.P. At rate of £150 and £100 respectively. Also Cas. O. £100.

Birmingham, Queen's Hospital.—Three H.P.'s, H.S., Anæsthetist. Also Dental H.S. Each £70.

Birmingham Union, Western House.—Asst. M.O. £500.

Birmingham University.—Asst. Lecturer and Demonstrator in Anatomy. £300.

Bootle Borough Hospital.—Two Jun. H.S.'s. Each at rate of £150.

Bradford Royal Eye and Ear Hospital.—Jun. H.S. £150.

Bradford, St. Luke's Municipal General Hospital.—H.P.'s. and H.S.'s. Each at rate of £200.

Burnley, Victoria Hospital.—H.P. At rate of £125.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

Canterbury, Kent and Canterbury Hospital.—H.S. At rate of £125.

Cardiff Royal Infirmary.—Radium Registrar. At rate of £200.

Carlisle, Cumberland Infirmary.—H.P. Also H.S. to Special Depts. Each at rate of £155.

Central London Ophthalmic Hospital, Judd-street, W.C.—Hon. Dental Surgeon.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Two Hon. Assts. to Out-Patient Dept.

Charing Cross Hospital, W.C.—Med. Reg. £150. Obst. Reg. £100. Also Registrar to Ear, Nose, and Throat Dept. £100.

City of London Maternity Hospital, City-road, E.C.—Res. M.O., also Asst. Res. M.O. At rate of £100 and £80 respectively.

Connaught Hospital, Orford-road, E.—Sen. Res. M.O. At rate of £150. Also Res. H.S. and H.P. Each at rate of £100.

Dartford, Kent, Darenth Training Colony.—Med. Supt. £1000.

Dewsbury County Borough.—Deputy School M.O., &c. £600.

Doncaster Royal Infirmary.—3rd H.S. At rate of £150.

Dreadnought Hospital, Greenwich.—Phys.-in-charge of Out-Patients.

Dudley, Guest Hospital and Eye Infirmary.—Asst. H.S. £150.

Eastern Dispensary, Leman-street, E.—Ophthalmic Surgeon.

East Ham Memorial Hospital, Shrewsbury-road, E.—Res. M.O. At rate of £200.

Evelina Hospital for Children, Southwark, S.E.—Hon. Surgeon to Out-patients.

Exeter, Royal Devon and Exeter Hospital.—H.P. At rate of £150.

Great Yarmouth General Hospital.—Sen. H.S. £180.

Greenwich Union.—Asst. M.O. £300.

Halifax Corporation Isolation Hospital.—Res. M.O. £350.

Hertford County Hospital.—Res. Surg. O. At rate of £250.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each at rate of £100.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Asst. Phys.

Huddersfield Royal Infirmary.—H.S. £150.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Ipswich, East Suffolk and Ipswich Hospital.—Two H.S.'s. Each £120.

Kent County Council.—Asst. M.O., &c. £600.

Kingston-upon-Hull, City Fever Hospital and Sanatorium.—Med. Supt. £800.

Kingston-upon-Hull, City and County of.—Tuberculosis Officer. £800.

Liverpool, Walton Institution, Rice-lane.—Res. Asst. M.O. £200.

L.C.C. Mental Hospitals Service.—8th Asst. M.O. £445.

L.C.C., Public Health Department.—M.O. £715.

Leicester Health Dept.—Temporary M.O. 10 gns. per week.

Leicester Royal Infirmary.—Two H.P.'s, also H.S.'s. Each £125.

London Hospital, E.—Med. First Asst. and Reg. £300.

Maidstone, Kent County Ophthalmic and Aural Hospital.—Ophth. H.S. At rate of £200.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

Manchester City.—M.O. for Maternity and Child Welfare. £600.

Manchester, County Mental Hospital, Prestwich.—Asst. M.O. £500.

Manchester Royal Children's Hospital.—Two Asst. M.O.'s for Out-Patients' Dept. Each at rate of £150. Also Res. Surg. O. At rate of £125.

Mile End Hospital, Bancroft-road, Mile End, E.—Res. Asst. M.O. £150.

Miller General Hospital, Greenwich-road, S.E.—Res. M.O., Cas. O., and H.P. At rate of £250, £150, and £125 respectively.

National Hospital for Diseases of the Heart, Westmoreland-street, W.—Res. M.O. At rate of £150.

Newcastle-on-Tyne, Hospital for Sick Children.—Jun. H.S. At rate of £100. Also Res. Sen. H.S. and Res. H.P. Each at rate of £95.

Northampton General Hospital.—Two H.S.'s, also Two Asst. H.S.'s. Each at rate of £150.

Northern Rhodesia, Roan Antelope Copper Mines, Ltd.—Jun. M.O. £900–£1000.

Plymouth City Mental Hospital, Blackadon, Ivybridge.—Med. Supt. £750.

Preston and County of Lancaster Royal Infirmary.—H.S. £150.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Res. Anæsthetist. At rate of £80.

Queen Mary's Hospital for the East End, E.—House Anæsthetist and H.P. At rate of £120.

Rochester, St. Bartholomew's Hospital.—Res. Radiologist. £150.

Royal National Orthopædic Hospital, Great Portland-street, W.—H.S. At rate of £150.

St. John's Hospital for Diseases of the Skin, 49, Leicester-square, W.C.—Sen. and Jun. Hon. Med. Registrars.

St. Mark's Hospital for Cancer, Fistula, and Other Diseases of the Rectum, City-road, E.C.—H.S. At rate of £75.

St. Paul's Hospital for Diseases of the Genito-Urinary Organs and Skin, Endell-street, W.C.— H.S. At rate of £150.

St. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C.—H.S. At rate of £75.

St. Thomas's Hospital, S.E.—Radium Reg. and Asst. to Radiological Dept. £250.

Salford Royal Hospital.—H.P., two H.S.'s, and Cas. H.S. All at rate of £125.

Sheffield, Jessop Hospital for Women.—Asst. H.S. At rate of £100.

Sheffield University, Dept. of Pathology and Bacteriology.—Asst. Bacteriologist. £300.

Southampton Free Eye Hospital.—H.S. £150.

Southampton, Royal South Hants and Southampton Hospital.—H.P. At rate of £130.

Stafford, Staffordshire General Infirmary.—H.S. and H.P. At rate of £200 and £100 respectively.

West Bromwich and District General Hospital.—H.S., H.P., and Cas. H.S. Each at rate of £200.

West London Hospital, Hammersmith-road, W.—H.P., Two H.S.'s and Res. Anæsthetist. Each at rate of £100. Hon. Asst. Surg., Hon. Med. Reg., and Hon. Obstet. Reg.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Four Chief Clin. Assts. Each 1 gn. per session.

Westminster Hospital, Broad Sanctuary, S.W.—Clin. Asst. to Dental Dept.

Willesden General Hospital, N.W.—Res. H.S. £100.

Willesden Municipal Hospital.—Res. M.O. £150.

Willesden U.D.C.—Two Dentists. £572 6*s.* 4*d.* Also Part-time Anæsthetist and Part-time Oculist. At rate of £300 and £225 respectively.

Windsor, King Edward VII. Hospital.—Res. M.O. £200. Also Sen. H.S. £140.

Births, Marriages, and Deaths.

BIRTHS.

Dodd.—On Feb. 11th, at a London nursing home, the wife of Charles Tattershall Dodd, L.D.S.R.C.S. Eng., of "Glen gowan," Thames Ditton, of a son.

Garfield.—On Feb. 13th, to Marguerite Garfield, M.R.C.S., L.R.C.P., wife of Montagu Garfield, M.R.C.S., L.R.C.P., L.D.S., of Palmeira Mansions, Hove—a son.

Tooth.—On Feb. 14th, at Clare House, Albion-street, Lewes, the wife of Dr. R. S. Tooth, of a daughter.

MARRIAGES.

Vere-Hodge—Walters.—On Feb. 14th, at Essex Church, Kensington, by the Rev. C. J. Street, M.A., LL.B., Gwendolen Sykes, daughter of Dr. and Mrs. Walters, of Pinecroft, Farnham, Surrey, to Harry Kirke Vere-Hodge, also of Farnham.

DEATHS.

Evans.—On Feb. 13th, Dr. John Evans, D.S.O., at Bryniau, Caernarvon.

Gough.—On Feb. 6th, at 3, Buckingham Gate, London, Elizabeth Marion Gilchrist, wife of Harold R. Gough, and only daughter of Dr. and Mrs. Anthony McCall, of Bournemouth.

Jordan.—Suddenly, after a brief illness, George Robert Leslie Jordan, M.B., B.Ch. (T.C.D.), High-street, Halstead, Essex, aged 34.

Llewelyn-Jones.—On Feb. 13th, from pneumonia, after a short illness, John Llewelyn-Jones, M.D., aged 57.

Moore.—On Feb. 11th, at Priory-road, Kew, Hubert William Moore, L.D.S.R.C.S. Eng.

Roche.—On Feb. 11th, suddenly, at Sheringham, Dr. E. B. Roche, aged 81.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

ESTIMATION OF DANGERS OF AVERTIN.

DETERMINATION of mortality-rates of anæsthetics is one of the least satisfactory of statistical exercises. The factors that may play a part in the causation of death during anæsthesia are so many and so variable that in any given case it may be impossible to attribute the end to any one or even to any two definite causes. It is not surprising therefore to find a vigorous defence put up against the accusations which H. Killian brought against the rectal anæsthetic, avertin. E. Glaesmer[1] shows that in the series of 16 fatalities associated with avertin which Killian had collected there was insufficient discrimination between various factors involved in the fatalities, and certainly not enough evidence to incriminate the anæsthetic per se. Obviously if the anæsthetic is held to account when death occurs after a formidable operation on a patient in the last stages of exhaustion a just view of the danger of that anæsthetic has not been taken. In fact any anæsthetic would come out of the ordeal with an equally unfavourable record. Again if patients who are unsuitable subjects for the anæsthetic succumb to its effects, the anæsthetic should not be burdened with the blame. We do not regard ether as dangerous because patients suffering from acute bronchitis succumb if they are subjected to long inhalations of the drug. Equally we must not blame avertin if fatality follows its employment on those who are suffering from severe disease of liver or kidneys. As E. Glaesmer properly points out, with every new anæsthetic we must learn its particular suitabilities and contra-indications, and until these are familiar and generally acted on it is little use trying to state a mortality-rate for the drug.

HALF-MINUTE THERMOMETRY.

Dr. H. W. Hales (Sheringham, Norfolk) writes: "Although thermometers are stamped by the National Physical Laboratory, Kew, as a guarantee of the accuracy of their reading, I have frequently found that a true reading is only obtained after five or ten minutes, when the instrument is stamped as a 'half-minute.' This seems to apply to the very subnormal temperatures, and not to any extent to those above 98·4° F. Seeing that temperatures of 95·6° to 96·6° F. are very much more common than is generally supposed, the matter seems to be of considerable clinical importance. Can you tell me the reason for this peculiarity? My own temperature frequently runs at a very subnormal level, so I have been able to test the accuracy of my statements on many occasions with many different thermometers, and controls have been made on numerous patients."

The Kew Certificate is no longer compulsory, but even a perfect "half-minute" thermometer can only give a correct reading in a cavity whose temperature is constant, such as the rectum. The temperature of the mouth, even in the alcove beneath the tongue, is affected by the currents of air which have recently passed through the mouth of the patient. This effect is so pronounced that a mouth reading, except in cases of fever, requires at least a minute, and often three minutes or more, to reach its proper level. Anyone can ascertain this for himself who will take the trouble of watching the mercury rise after the thermometer has been placed in the patient's mouth. When the surrounding atmosphere is cold the correct mouth reading is still more delayed, and in alpine sanatoriums where mouth temperatures are taken it is often the rule for the thermometer to remain in situ for ten minutes, whatever may be the length of time that the thermometer itself takes to register. On the other hand, a "three-minute" thermometer will give a correct reading in half a minute in the rectum, or in still shorter time in the stream of urine. Briefly a "half-minute" thermometer requires a "half-minute" medium.

DOCTOR'S CONSULTING ROOMS AT CHEMISTS' SHOPS IN SOUTH AFRICA.

THE following resolution passed by the Associated Pharmaceutical Societies of South Africa was submitted at the annual meeting of the South African Pharmacy Board, held at Bloemfontein, on Jan. 15th: "That the Medical Council and Pharmacy Board be asked (*a*) to take steps to prevent medical practitioners from having consulting rooms attached to chemists' shops, and displaying their name-plates on the chemists' premises; (*b*) to debar the use of prescription pads and envelopes which have the name and address of a chemist printed thereon." The Registrar explained that the Board at its last meeting decided to ascertain the views of the Medical Council on the subject. This was done, and the reply of the Medical Council was to the effect that it was not prepared to do anything in connexion with the first point. With regard to the second, the Medical Council had decided to make it one of the matters which would be liable to the Council's disciplinary powers. Mr. J. Christie, M.L.A., the Chairman, announced that the Bloemfontein chemists had notified him that they were opposed to the Board taking any steps relative to the question of consulting rooms and name-plates of medical practitioners attached to chemists' premises on the ground that the matter rested with the Medical Council. After discussion it was agreed to notify the Associated Pharmacy Societies that the Board "considers both practices undesirable." It realised that the first-mentioned practice was one of very long standing, but considered that it would in time die out of its own accord. With regard to the second practice, the Board would like to see this cease at once.

METALIX TUBES.

A 35-page brochure on Metalix X-ray tubes is issued by Philips Lamps, Ltd. (145, Charing Cross-road, London, W.C.2), and will be found of value to users and potential users of these tubes. The first 15 pages are devoted to an account of the general aim of the makers to supply the varying requirements of radiographic work; three tubes have been produced, known as 2·5, 6, and 10 kw., an adequate description of the conditions under which each should be worked and maintained being given. The brochure also contains valuable information on design, working efficiency, and cost to which reference might with advantage be made by those engaged in radiographic work.

MANIC-DEPRESSIVE PSYCHOSIS.

Sir Robert Armstrong-Jones, who presided at the meeting of the Section of Psychiatry, Royal Society of Medicine, on Feb. 11th (reported on page 353 of our last issue), would have made the following concluding remarks had time permitted:—

Manic-depressive insanity expresses the whole of the symptom-complex. The "entity" was first described by Fabret as "folie circulaire," and later by Kraepelin by its present title. It has nothing to do with neurasthenia, but much with heredity. It is merely an exaggeration of the normal mental rhythm, and of all the mental abnormalities it is the one best known to the family doctor; only in its severer forms is it known to the specialist—whether he is styled neurologist or psychiatrist—and only in its gravest forms does it come under certificates. Those not conversant with insanity cannot realise the dread of a relapse felt by the sufferer, and something must be done for him. Bevan Lewis attributed its pathology to some metabolic change in the cortical neurons; melancholia being a slight change and mania a deeper one, but of the same kind, and constituting what he described as a state of *labile equilibrium.*

The disease always comes on suddenly, without prodromal symptoms (unlike ordinary mania and melancholia). There *are no hallucinations or delusions, and for this reason* it has been called *mania* (or *melancholia*) *raisonnante.* There is complete return to lucid intervals—a complete *restitutio ad integrum*, and no dementia follows. The treatment aimed at is to break the habit (or, as Savage said, "abort" the rhythm). The first thing the physician always does in every disease is to change the diet. A strong aperient, such as calomel, jalap, or the stronger salines may stop an attack. Bromides are absolutely necessary to "jam down" or repress hyperæsthetic centres. Long immersion baths may help.

A THERMO RADIO PAD.

Radium Electric Ltd., of 24, Grosvenor-gardens, London, S.W.1, have submitted for our inspection an electrically heated pad which serves as a portable and equable source of heat, the effect of which is enhanced by radium emanation. The radio-active substance which is safely embedded in the pad is of a standard guaranteed by the Radium Institute of Vienna to be not less than 0·01 mg. per pad. The wiring is insulated in asbestos, and a three-way switch provides further maintenance of three different constant temperatures, a thermostat automatically cutting off the current when the desired heat is reached. The whole is enclosed in a damp-proof layer of Billroth tissue with a washable linen cover. The pad can be supplied for any voltage, and has simply to be affixed by its wire to any available lamp-bracket or wall-plug. The running cost, even at 6*d.* per unit of current, only amounts to about a penny for four hours. The general construction of the pad has also been tested at the Faraday House Laboratories, and is described as satisfactory. The cushion, which is briefly described as the "Q-Ray," costs three guineas, and may be had direct from the manufacturers, or from chemists and electrical dealers. A number of the pads are stated to be in use at various hospitals and sanatoriums in Vienna, and their application is suggested in such conditions as lumbago, neuralgia, sciatica, or any painful inflammatory condition.

Hunterian Lecture

ON

RADIUM TREATMENT OF CARCINOMA OF THE BREAST.

Delivered before the Royal College of Surgeons of England on Feb. 3rd, 1930.

BY GEOFFREY KEYNES, M.D. CAMB.,
FELLOW OF THE COLLEGE; ASSISTANT SURGEON TO ST. BARTHOLOMEW'S HOSPITAL.

THE history of the use of radium in treating carcinoma of the mammary gland is necessarily brief, and, indeed, only since 1920 has its application come to be regarded as anything more than a palliative for those unhappy patients in whom no operation was feasible.

It will clear the ground if I indicate broadly the three possible methods of using radium in this disease.

1. It may be applied externally in the form of plaques or as batteries of needles over a diffracting medium, such as the mixture of wax and sawdust known as Columbia paste.
2. It may be applied at a distance, using the beam of rays from a mass of radium contained in the so-called "bomb."
3. It may be buried in the tissues in suitable containers.

It is only with the last of these methods that I shall deal, as circumstances determined that this method was the one which we chose to use in the first place for our investigation, and we have used it consistently ever since. Had there been no other reason in its favour, the use of interstitial irradiation was to be preferred, as it is by far the most economical of radium.

The first treatment by this method given by the Surgical Professorial Unit at St. Bartholomew's Hospital under Prof. G. E. Gask took place in 1921. After three years' experience it became clear that recurrent nodules could be made to disappear by interstitial irradiation. In logical sequence the first treatment given to a patient with primary carcinoma of the breast took place on August 1st, 1924. Up to the present time 154 patients with primary carcinoma of the breast have been treated, and as far as I know no comparable series of radium treatments has been described at any other clinic in the world.

SURGERY OF THE BREAST.

The history of the surgery of carcinoma of the breast has been, as in the surgery of most other parts of the body, that of a progression from crudity to refinement; there has also been a progressive increase in the extent of the operation up to the anatomical limits of accessibility. This has been influenced chiefly by increased knowledge of the lymphatic drainage of the breast, and the foundations of this knowledge were laid by Sappey about 1885. Before this, in 1878, Halsted, of Baltimore, had emphasised the frequency of lymphatic extension to the glands above the clavicle and in the anterior mediastinum. He had even advised a routine resection of the clavicle, and removal of the tissues above it and below, and Harvey Cushing, working in his clinic, had also removed the glands from the anterior mediastinum in a few patients, but neither of these procedures has been generally used. The third special contribution in this field was made by Sampson-Handley, whose theory of centrifugal permeation has greatly influenced procedure in the direction of removing at operation more skin and more deep fascia, until a great part of the chest wall has been denuded. At the present time most surgeons content themselves with a wide removal of skin, a wider denudation of the chest wall, including removal of the pectoralis minor and the greater part of pectoralis major, and a careful dissection of the vessels in the axilla. The degree of mutilation necessitated by this operation is undeniably great, though the disability caused by the removal of the pectoral muscles is less than might be expected. A frequent complication has been œdema of the arm resulting from interference with the lymphatic drainage. In spite of the severity of the operation, operative mortality has been low. Final results have proved very difficult to assess, and with so many variable factors the published figures have differed within wide limits. In my own experience the results obtained in unselected cases, none being rejected except such as were obviously "inoperable," have not been good. It has been borne in upon me by observation of my own patients and those of other surgeons that frequently the disease is actually disseminated by the operation, secondary growths appearing in the surrounding skin or at a distance more quickly and more widely than if the patient had had no treatment at all. It is possible that dissection with the diathermic current instead of with the ordinary scalpel may, to some extent, prevent this, but I believe that any operative interference may stimulate to activity many carcinoma cells which would otherwise have remained quiescent. I have made these brief remarks upon surgical treatment partly to outline its principles, partly to suggest that, although there is always likely to be a considerable field for pure surgery in mammary carcinoma, it is reasonable to consider whether there may not be a better alternative—namely, radium.

TECHNIQUE OF RADIUM TREATMENT.

The form of radium treatment that we have used at St. Bartholomew's has been based strictly upon surgical principles. It has consisted in the burying of platinum needles containing radium in such a way that both the primary growth and every accessible area of lymphatic drainage has been subjected to adequate irradiation. The details of technique have already been fully described elsewhere.[1] I need only indicate here the usual distribution of radium needles: (1) beneath the breast itself, (2) beneath the pectoral muscles, (3) in the axilla, (4) on the costocoracoid membrane, (5) above the clavicle, (6) in the upper three or four intercostal spaces. It will be seen from this that radium needles may be divided into two main groups, those in relation to the mammary gland and the primary growth, and those in relation to the lymphatic drainage. The needles of the second group are placed as a routine in the positions indicated. Those of the first group are a highly variable quantity, the size of the tumour and of the mammary gland, and therefore of the area to be covered, varying within wide limits. The second variable factor is the time of exposure, and this has been arrived at empirically by trial. Experience has shown that the optimum time is about 168 hours—that is, seven days—and it is seldom necessary to depart from this standard, which has obvious advantages in facilitating hospital organisation. Thus the main principle has been a prolonged exposure to a relatively small dose of radium, the same principle which has been extensively used in other parts of the body. The relatively small size of the dose might arouse doubts as to whether adequate penetration of the rays is being obtained. For, although we may occasionally place a few needles in the plane of the main mass of growth, most of the needles are purposely put deep to it, and so usually deep to the mammary gland, partly because pushing needles into a growth may cause necrosis, partly because carcinoma cells might be displaced and disseminated, partly because the tissue is often so tough that damage to needles may result, and finally because in practice it appears to be unnecessary to place them in the growth. In many cases the mass of growth has been so thick that clearly the cells further away from the radium can only have received a fraction of the intensity directed upon those close to it, and often the intensity must have fallen below what was theoretically necessary to constitute a lethal dose, and yet the whole tumour has disappeared. Actually, therefore, it seems that the length of the time factor compensates for lessened intensity, and probably there are other biological factors of which we are still unaware. In this connexion it is of interest to note that acquired insensitivity to the radiations, which has been so much of a bogy in the past, has not in this investigation been found to have much importance. Patients have received as many as four treatments, and usually the growth has responded as well on the later occasions as it did on the first, so that a very large growth has been caused to disappear in successive stages.

---

[1] St. Bartholomew's Hospital Reports, 1927, lx., 203; THE LANCET, 1928, ii., 108; Acta Radiologica, 1929, x., 393.

This has been illustrated by the case of a patient first treated in July, 1926, for a large mass of carcinoma occupying the whole of the right breast and filling the right axilla. She had two further treatments at intervals of eight months with progressive improvement until no growth remained. In July, 1929, she was treated a fourth time for a small skin nodule just outside the area treated, and now, three and a half years after first being treated, she is without external signs of disease.

DIAGNOSIS.

In judging the value of any new form of treatment a properly critical mind will require some scientific proof that the condition treated was actually the disease that it was stated to be. With this in view, I set out to remove a specimen for section from every patient, taking the precaution to do this after the growth had been irradiated, when the cells might be supposed to have a diminished power of growth, and I hoped thus to avoid causing any dissemination of the growth by cutting into it. This proved to be an interesting experiment upon the biological side of the problem, for I proved that carcinoma cells, which would have disappeared had they been left undisturbed, were yet able to grow if transplanted to new surroundings. In other words, in more than one case, although the original tumour disappeared, an implantation growth appeared in the incision through which the specimen had been removed, and this had to be separately treated afterwards. In one patient this was disastrous, the implantation growth proving much more resistant than the original tumour. It was therefore clear that removing a specimen, though scientifically desirable, was contrary to the patients' best interests, and after proving that carcinoma was present in 50 consecutive patients I abandoned the practice as a routine. I thought it better to make an occasional mistake and treat a patient with radium who had not got carcinoma than to endanger the result in all of them. Actually I do not think any mistakes have been made, for the diagnosis of carcinoma on clinical grounds is seldom in doubt. If I felt uncertain, I either excised the lesion first, or else I placed the patient in a different category from the others for statistical purposes, and they are not included in my series.

RESULTS.

Surgical removal of a carcinoma of the breast results in the immediate and complete disappearance of the tumour, with consequent relief to the patient's anxieties. The psychological attitude after radium treatment has to be somewhat modified, for no miracle results, and after the needles have been removed the tumour is still there. It is important, therefore, for the patient's peace of mind to be able to give some prognosis of the probable course of events. Experience has shown that there is always an obvious change in the size of the tumour within two or three weeks. After two months it may have shrunk to half its original size, and within three months a small tumour may have completely disappeared. If the tumour is large, it sometimes happens that it goes on shrinking for much longer than this, but after a time, perhaps six to nine months, appears to be stationary. A doubt will then arise concerning the residual tumour, as to whether it still contains active carcinoma cells or whether it consists only of the fibrous matrix originally present. When this occurs I believe it will usually be wise to give a second radium treatment, which may result in further shrinkage or even disappearance of the tumour. If little change results, it is probable that the tumour consists only of fibrous connective tissue, as has been proved in more than one patient by subsequent local excision and histological examination. In spite of this, excision of a residual tumour should be done, for even after two treatments carcinoma cells may have survived on the surface which were screened from the rays by a great thickness of fibrous tissue forming the greater part of the residual tumour. From these specimens interesting information as to the action of radium on the carcinoma may be obtained, and this is illustrated by the following.

CASE 1.—A patient had a large mass of carcinoma adherent to the chest wall and inoperable. She received treatment in February and June, 1927, and there was very great improvement, but in November there was still a hard lump remaining, and this was excised. A section right through it shows disappearance of carcinoma cells except for some unhappy-looking remnants on the surface. The whole of the rest of the mass consists of fibrous tissue only. This patient is free from external recurrence three years after being first treated.

CASE 2.—A patient was first treated in May, 1926, after excision of a doubtful lump. Recurrence took place ten months later, and the growth was again treated. Five months later a residual mass was excised and was found to consist of fibrous tissue only. The patient remains well three and a half years after being first treated.

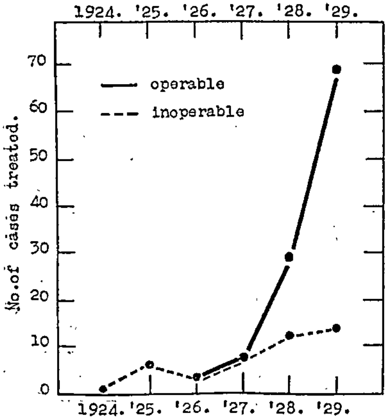
CASE 3.—A lady, aged 77, with a very large mass in the breast was treated in June, 1928, and a residual mass was excised six months later. Section showed that this consisted entirely of fibrous tissue, though "ghosts" could still be seen indicating the structureless remnants of some of the groups of carcinoma cells. This patient is quite well 19 months after being first treated.

Sometimes surgical excision may be contemplated for other reasons. The bulk of the tumour may have gone, and an ulcer, originally large, may have shrunk to a small size, retaining, however, a rim of little nodules around it. Local removal can then eradicate the disease; section proves the survival of some groups of carcinoma cells, but the disease does not recur, as is illustrated by the following case.

A patient was treated for an ulcerated carcinoma in September, 1927. A small residual ulcer was excised four and a half months later, and carcinoma cells were found, as was expected, immediately surrounding it. The patient is quite well two years and four months after being first treated.

These remarks will have indicated that there is still an important place for surgery in combination with radium treatment, but only individual experience can make the decision as to when it must be brought into play.

Before embarking upon an extensive radium treatment of unselected patients with carcinoma of the breast, it was clearly necessary to form some estimate of its possibilities. Patients were accordingly chosen first among those who had external recurrences following operation. It was shown that these recurrences could easily be made to disappear, though the patients' lives were seldom prolonged. In fact, of 22 patients treated in the years 1921–28 only two have survived to the present time. One of these patients, however, treated in 1926 for a large recurrent growth, is without signs of disease, and has been so for nearly four years. The local results obtained in these patients seemed to justify the extension of the treatment, and in August, 1924, the first patient with primary carcinoma of the breast received radium treatment. She was suffering from an ulcerated scirrhous carcinoma, which was adherent to the chest wall, and therefore inoperable. She received what would now be regarded as an inadequate dose, but the ulcer healed and the tumour was greatly reduced in size. A second treatment was given four months afterwards, and seven weeks later the area was excised. The patient remained quite well for five years and then developed a small nodule in the skin of the areola just outside the part treated. This has been irradiated, and the patient is at present without signs of disease. From this beginning in 1924 an increasing number of patients have been given radium treatment each year by the Surgical Unit at St. Bartholomew's under Prof. Gask and myself, and this progression is seen on the accompanying graph. A total of 154 patients has been treated to the present time. This is evidence of increasing confidence on the part of the surgeons concerned, an increase which is further illustrated by the splitting of the graph into two lines indicating the numbers of inoperable and operable cases. The terms "operable" and "inoperable" are hard to define, and their application must obviously depend upon the individual judgment of the surgeon in charge. "Inoperable" may be understood, however, to mean in general that no surgical treatment could hope to eradicate the disease, even locally; "operable," that there was a reasonable expectation of complete local removal by operation, though this has been interpreted somewhat liberally. In the present state of knowledge it is clearly of importance to maintain the somewhat artificial and arbitrary distinction between operable and inoperable cases. Few surgeons who have been accustomed to operate for carcinoma of the breast and have obtained a high survival rate in early cases will consent to use radium instead of operation, unless they can be satisfied that radium will give results at least as good. A comparison of results in operable cases must therefore be made available when a long enough time has elapsed.



The total survivals among the 149 patients treated to the end of 1929 is as follows:—

	Treated.	Alive.
Operable	108	101
Inoperable	41	22
Total	149	123

The survival rate is further analysed in the following table.

The survival rate among inoperable cases must of necessity be relatively low, though actually, considering that all these were patients whom surgery could not have helped, the survival rate is surprisingly high. Among the operable cases only five patients are dead out of 110 treated during four years, though it must be pointed out that more than half of these were treated a year or less ago.

It must not be supposed that every one of these patients has had radium treatment only, nor necessarily on only one occasion. Thus, in 13 patients a lump had been locally removed before the radium was inserted. Usually an interval of three or four weeks was allowed to elapse in order that sound healing might take place, and then the radium was inserted in exactly the same way as if the tumour was still there. Recurrence has taken place in only one patient, and this was successfully dealt with, so that this procedure does not seem to be absolutely wrong, though to be avoided if possible.

Table showing Analysis of Survival Rate.

—	Operable.			Inoperable.		
	Cases treated.	Now alive.	Without apparent signs of disease.	Cases treated.	Now alive.	Without apparent signs of disease.
1924 ..	—	—	—	1	1	?
1925 ..	—	—	—	6	1	1
1926 ..	3	1	1	3	3	3
1927 ..	7	6	3	7	4	4
1928 ..	29	26	13	11	5	0
1929 ..	69	67	39	13	8	0

In 13 patients a residual swelling has been locally excised some time after radium treatment had been completed. These patients form a group of relative failures, the excision having been undertaken because carcinoma was known to be still present, or owing to uncertainty as to the nature of a residual tumour. Some of these cases have already been referred to in describing the histology of tumours after irradiation, and it was mentioned that carcinoma was found to be still present in some of them. Nevertheless, of these 13 patients eight are alive and without signs of disease.

Three patients had already had a radical operation performed for carcinoma of the breast, and radium was inserted as a form of prophylactic treatment. All of these are free from signs of disease, though this cannot be ascribed with any confidence to radium!

X ray treatment after radium has been given to 11 patients. These were all relative failures, the X rays being given because of recurrences or an incomplete disappearance of the growth.

A total, therefore, of 109 patients have had radium treatment only.

Reference has already been made to the supposed occurrence of acquired insensitivity of carcinoma to irradiation as a result of repeated treatment. These remarks were founded on the experiences of the following patients: 23 had two treatments; 3 had three treatments; 2 had four treatments.

The following are characteristic examples of successful treatment.

A patient with a small scirrhous growth adherent to the chest wall was treated in May, 1925. Three months later the tumour had disappeared, and the patient is quite well over four and a half years after this single treatment. Another patient had a growth of moderate size dimpling the skin of the left breast; treatment was given in November, 1927, and four months later the lump was gone. Rather more than a year after treatment she proceeded to give its efficacy the severest conceivable test by becoming pregnant. Confinement, lactation, and nursing took place normally, and the patient is quite well two years after treatment. The presence of carcinoma in this patient was proved by section.

CAUSES OF OCCASIONAL FAILURE.

I do not wish to convey the impression that the treatment is never attended by real failure, though such cases have been surprisingly few, apart from the inevitable wastage of patients due to visceral or skeletal metastases, and to intercurrent disease.

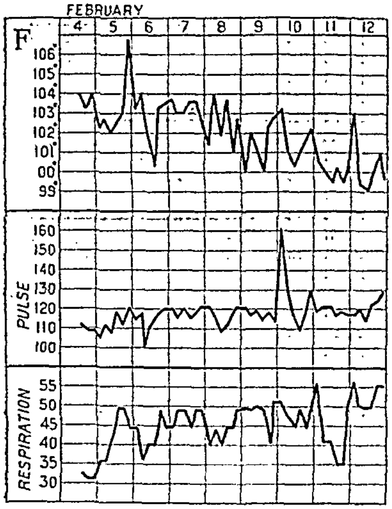
CASE 7.—Saw the parrot daily, and tried to catch it on one occasion, but did not actually handle it.

CASE 8.—Son of Case 7. Never entered the flats nor had any direct contact with the parrot.

A Second Fatal Case.

CASE 9.—Male, aged 60, had lived in China and Egypt 25 years ago where he is said to have had malaria and typhoid fever. Six years ago he developed carcinoma of the larynx which was successfully treated by radium. He purchased 8 parrots on Dec. 11th, 1929, and 2 budgerigars and 2 monkeys on the 24th. The parrots were wild, so it is possible that infective material was wafted to some distance from the cage. A parrot died on Dec. 26th, a love-bird about the 29th, another parrot on the 30th, and a third on Feb. 6th, 1930. The patient himself buried those birds which died before the onset of his illness. The daughter admits to picking up feathers of the bird which died on Dec. 26th; on Jan. 10th she developed a disease having the symptoms, signs, and course of pneumonia; yet with temperatures 103°–104° the pulse was 84–90, respirations 22–24.

CHART 6 (Case 9).



Clinical History.—On Jan. 22nd and the two following days the patient complained of headache in the evening on return from work. The incubation period is impossible to assess with certainty; it may have been as long as 28 days. On the 4th day he shivered; temperature found to be 104° F. Slight cough was present; sputum small in quantity, frothy, mucoid, never coloured. A little later, and for some days, the cough was often followed by vomiting which was also easily induced by inspection of the throat or the presence of a thermometer in the mouth. Headache was severe on the 5th and 6th days, and general aching of the body was also a complaint. There was no epistaxis.

When first seen by one of us with Dr. S. T. Harris on the 9th day of his illness the patient was flushed, but beyond the temperature of 103° F. a pulse of 90, and the rash, no physical signs could be found to account for his illness. The pulse was not dicrotic, and the knee-jerks were normal. He resented being kept in bed, and it is stated that at night he used to leave his room in search of food. On the 14th day he was admitted to St. Bartholomew's Hospital. The general tendency of the temperature in the succeeding days was to fall, and the pulse and respiration frequency to rise (Chart 6). Delirium, at first nocturnal, was present from the fourth night; in the earlier stages he moved his arms as though driving a car. By the end of the second week, though still able to recognise individuals for short periods, he was very talkative—a happy delirium in which correct sentences were used but without sensible context. Later, a low muttering delirium as he sank into the typical "typhoid state" in which death occurred on the 22nd day of the disease.

Rash.—On the 9th day, for 24 hours only; confined to the trunk, around the lower costal margin and flanks. Spots about 20 in number, 3 or 4 mm. in diameter, red-brown, circular or square, sharply defined, just raised, fading on pressure; more plaque-like and darker in colour than the classical "rose spot" of typhoid fever.

Other Physical Signs.—The spleen was not palpable, and there was no enlargement of superficial lymph nodes. The tongue was moist in the earlier stages, its surface covered with a white fur except at the edges; it became more dry and brown as the illness progressed. The throat was injected, but showed no exudation. The abdomen gradually became distended during the third week, but at no time was tympanites excessive. The bowels were constipated in the early stages; for two days after the intravenous injection of 5 c.cm. of 1/1000 perchloride of mercury he suffered from diarrhœa; the stools were pale in colour and offensive, but contained no macroscopic blood or mucus. Much flatus was passed. From the 16th day he was incontinent.

The pulmonary breath sounds at all times were weak, perhaps because of emphysema. During the second week rhonchi and fine râles were audible at the right base. About the 15th day similar signs developed at the left base with impairment of percussion note; it was only on the day before death that the breath sounds became bronchial, and then only in small areas on the left side. At no time was friction heard. The cough and quantity of sputum greatly diminished during the third week. There was some hiccough towards the end.

Clinical Pathology.—On the 9th day the white cell count was 7200 per c.mm. On the 16th day white cell count was 8800 per c.mm., and reds 5,100,000. Colour-index 0·8.

Blood Cultures.—9th day and 14th day in broth and in bile gave no growth. Agglutination: Serum failed to agglutinate in dilution of 1/25 to 1/250 on incubation at 55° C. for 24 hours *B. typhosus*, *B. paratyphosus* A and B, *B. aertrycke*. *Vomit* containing bile was cultivated; no organism of the typhoid or the salmonella groups was isolated. *Throat swab* yielded no hæmolytic streptococci, or any Klebs-Löffler bacilli. *Sputum* (17th day) was mucoid with a few purulent flakes. Films and cultures showed pneumococci, and a few streptococci of the salivary type. *Urine* contained a trace of albumin. No bacilluria or pyuria. *Stool* (10th day): Liquid brown material, faintly acid in reaction. Gram film showed coliform bacilli, streptococci and anaerobes in the usual proportions. An organism which did not ferment lactose was present in small numbers. It was not agglutinated by the patient's serum or by any type serum of the typhoid or salmonella groups.

Treatment.—The patient was treated on general lines as a case of typhoid fever. On the 15th day he was given intravenously 5 c.cm. of 1/1000 hydrarg. perchlor. in 600 c.cm. of saline. A rigor ensued in less than one hour, the temperature rising from 103° to 106·8°; in four hours it had fallen to 101°. No apparent benefit followed this pyrexial reaction. *Serum:* Though the daughter's illness was diagnosed as pneumonia it was thought possible she might have been a case of psittacosis. As the patient's condition was steadily worsening he was given 12 c.cm. of his daughter's serum intramuscularly on the 16th day, 18 c.cm. on the 20th day, 15 c.cm. on the 21st day, and 20 c.cm. on the 22nd day. No apparent benefit. The application of dry cups, followed by a linseed poultice, to the left base was without obvious effect on the pulmonary condition.

Morbid Anatomy in the Two Fatal Cases.

The striking changes in both fatal cases are in the lungs. The pleuræ have lost their lustre, and a thin layer of fibrinous exudate is present over the greater part of both lungs. This exudation can be peeled off without difficulty. Small hæmorrhages are present beneath the visceral pleura, particularly towards the base; there is no free fluid in the pleural cavity. The lungs are not greatly swollen and do not bear the imprint of the ribs. In the woman (Case 3), on the surface of the lung, chiefly in the lower lobes, are a number of bosses, dark red in colour, firm to the touch, varying in diameter from ½ to 2 inches. Immediately surrounding these areas is a narrow bright red belt, the whole having much the appearance of a lung containing a number of septic infarcts all of recent origin. On section (Fig. I., special plate) it is found that the slightly raised areas already referred to are areas of consolidation, reddish-grey in colour, and bounded by a deep red margin. Other similar areas are seen in the depth of the lung, the intervening parts of which are brownish-grey in colour and gelatinous in consistency. A small hæmorrhagic infarct is present in the right lower lobe. In the left upper lobe the consolidated areas are more grey in colour, and appear to be of longer standing than elsewhere. There is no breaking down of lung tissue, and no purulent secretion in the bronchioles though the trachea and main bronchi are injected and contain some muco-pus. The bronchial glands are swollen and firm.

In the man (Case 9), the upper two-thirds of the left lower lobe and the right upper lobe are for the most part solid. In both lobes are grey asbestos-like areas, mostly granular to the touch, surrounded by a bright red margin (Fig. II). Other areas sharply defined present a more structureless appearance like that of an ischæmic infarct or the "white pneumonia" of congenital syphilis. There is much gelatinous œdema, but no purulent exudation and no softening. The trachea and bronchi are injected. The bronchial glands are not enlarged. The spleen in both cases is slightly enlarged; congested but not soft. The other viscera show cloudy swelling and congestion. An intramuscular hæmorrhage of recent origin is present in the abdominal wall of Case 9. It is not at the site of a serum injection. The bowel contents are fluid, and in the cæcum are four small shallow acute ulcers, the peritoneum over which is natural.

The *histological study* of the changes in the lungs demands more detailed investigation. Yet the preliminary stage in the examination already shows certain peculiar features.

In both cases the main condition may be described as a broncho-pneumonia, the cytology of the alveoli in the actual areas of consolidation showing no unusual characters. Neighbouring areas of lung are œdematous. In addition there are small foci of suppuration and in some places there are areas of complete necrosis. In Case 3 (Figs. III. and IV.) one of these areas is at the periphery of the lung and the presence of a thrombosed artery at its apex suggests that it may be an infarct. However, thrombosed vessels are seen in other parts of the lung, without adjacent necrosis. A further peculiarity in this case (3) is the presence in the lung of plugs of coagulated material in many of the alveoli. These are of regular, circular, or oval shape, and contain no cells except shed alveolar epithelium bordering them. No structures exactly comparable with these have yet been seen in the second case.

General Remarks.

The study of the cases hitherto reported under the provisional name of psittacosis, together with these here recorded, makes the conclusion almost irresistible that there is a septicæmic form of disease in human beings closely associated in causative fashion with disease in parrots and kindred birds. This conclusion is borne out alike by the clinical features of the disease, by the peculiar morbid anatomical findings—especially in the lungs—in fatal cases, and by the evidence of contact, direct or indirect, with sick or dead parrots.

Amongst the clinical features in the series of cases here noted the prevalence of epistaxis during the early stage of the disease, the tendency to diarrhœa with collapse, and the special liability to pulmonary complications towards the end of the first week are noteworthy. If the cases are to be accepted as a group in which the infection is of the same order throughout, it is clear that the disease may be in some instances extremely severe, carrying a very grave prognosis, and in others quite mild. There is also some suggestion that age is a factor in prognosis, in that the severest cases have been in patients over 30 years of age. There appears to be no recorded case of a severe illness in a patient under 20 years of age. Case 8 in the present group, a boy of 11 years, was very mild, as was the case in a boy of 7 years, the youngest in Dr. A. P. Thomson's series of 21 cases.[1]

In considering the *differential diagnosis* the acuteness of the onset with headache, general pains, anorexia, and insomnia very naturally suggest influenza. In neither disease have we any diagnostic criterion either as regards physical signs, clinico-pathological findings, or bacteriological tests. Absence of leucocytosis marks both diseases, at all events in their early stage. Epistaxis or delirium occurring during the first few days should raise suspicion that the case is not influenza. The similarity between the diseases may obviously be so close that further knowledge can alone help us to decide how many cases labelled "influenza" properly belong to this more recently studied infection. Although it is no doubt true to say with Dr. Thomson that the outstanding features of psittacosis are consequent on the pulmonary involvement, it must be remembered that this is also true of the more severe cases of influenza. If, however, in a doubtful case, pulmonary signs appear during the first three days the diagnosis of influenza is the more probable. On the other hand, an influenza-like disease which persists for more than five days without pulmonary complications should lead to inquiries, *inter alia*, concerning sick birds. From the enteric group psittacosis is marked off in the main by its more abrupt onset, negative blood culture in the early days; the absence of an agglutination reaction in the second week, and the rarity in typhoid nowadays of pulmonary complications other than signs of slight bronchial catarrh. General tuberculosis will sometimes present a difficulty, but here again the onset is likely to be less acute, the pulse frequency raised more in proportion to the temperature, and the appearance of toxæmia, as expressed by the facies, anorexia, and delirium, less marked than in psittacosis.

In the matter of the incubation period of psittacosis no reliable evidence is afforded by a study of the cases here reported. They do suggest, however, that it is not less than ten days.

We desire to express our thanks to several of our colleagues—to Drs. James Maxwell, R. S. Johnson, and L. P. Garrod for pathological investigations; to Dr. E. R. Cullinan for his preliminary report on the histological appearances in the lungs; to Dr. E. L. Sturdee (of the Ministry of Health) for sundry communications; and especially to Dr. Desmond Urwick for his careful analysis of the group of eight cases recorded in the text, and his permission to make use of his notes.

PULMONARY ASBESTOSIS.

BY W. BURTON WOOD, M.D. CAMB.,
M.R.C.P. LOND., D.P.H.,
PHYSICIAN TO OUT-PATIENTS, CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK, E.;
AND
S. ROODHOUSE GLOYNE, M.D. LEEDS, D.P.H.,
PATHOLOGIST TO THE HOSPITAL.

ALTHOUGH asbestos and asbestos products have been used in industry for a long time, it is only during the last few years that pulmonary asbestosis has been recognised as a serious industrial disease.

Asbestos, which was known to the ancient world, is a silicate occurring in minerals in combination with iron, copper, calcium, or magnesium. It is quarried or mined in various parts of the world; Italy and the Mediterranean, South Africa, Rhodesia, Canada. In its natural state it occurs in strands of long silky fibres which are highly resistant to heat, strong acids, and alkalis. These masses are usually broken up into short lengths before exportation into this country. In this country the lengths are crushed and disintegrated and then either mixed with various substances for hardening into slabs, pipes, boards, &c., or carded, spun, and woven into various products like mats and mattresses, or used as an inert diluent or filling of a heat-resisting character. At certain stages in these industrial processes dust consisting of fine asbestos fibres is generated. When examined microscopically by dark-ground illumination the asbestos fibre gives the impression of a sharp, brittle metallic wire broken off at various angles and in different lengths, and, being highly refractile, has the appearance of the glowing filament of an electric bulb. These fibres can be found in the nose and mouth, and in the asbestos corns and minute skin lesions of the workers. On reaching the lung the fibres set up a pneumonokoniosis of a characteristic variety.

---

[1] THE LANCET, Feb. 22nd, p. 396.

show subsidiary bosses on it or may be broken off altogether or splintered in small bits. The segments may be closely contiguous like those of a crustacean, or they may be separated by a clear interval, and they are not infrequently fragmented. They vary in size and may be rectangular or oval. Occasionally sausage-shaped forms of the asbestosis body without any constrictions are found. Also what appear to be early forms can be detected. These look like thickened fibres with a slightly bulbous head, and they often are of unusual length, rather suggesting that once the asbestosis body is fully formed it tends to get fragmented. The bodies do not stain with the ordinary aniline dyes, but can be faintly stained with the prussian blue reaction used for detecting iron in histological sections. They are resistant to antiformin and to weak acids, and we have found them, in sections, to resist weak decalcifying fluid for many days. We have also found them to resist desiccation and autolysis in sputum for at least a week.

Once seen the asbestosis body can be readily recognised, and we know of no other substance found in human histology with which it can be confused.

Suggested Classification of Stages of Pulmonary Asbestosis.

Pulmonary asbestosis falls into group B [1] of occupational diseases of Bridge's classification.[11] Three stages can be defined: (1) the presence of asbestos fibres in nasal secretion or in the mouth, merely indicating exposure but not necessarily disease; (2) the presence of asbestosis bodies which is a sign of a tissue response to the infecting dust; (3) the typical symptoms, signs, and X ray appearances which are, in addition, clear evidence of the disease irrespective of the finding of asbestosis bodies.

Obviously (1) is no evidence of disease, but we can accept (2) as a sign that disease is present. In the absence of sputum diagnosis must be made on (3) alone. There remains, of course, the difficulty of a patient with pulmonary fibrosis of childhood origin, subsequently becoming employed in an asbestos factory. We consider the radiogram would be sufficient to distinguish this type of case from true pulmonary asbestosis.

Lastly, there is the question of pulmonary tuberculosis as a complication. Does the occupational disease light up quiescent tuberculosis or does tuberculosis become implanted on pulmonary asbestosis as a terminal event? It is impossible to decide this question, but it is worth while noting that when pulmonary tuberculosis does occur in these cases it is liable to be of an anomalous type.

We are indebted to the Medical Staff of the hospital for permission to use their cases, to the Staffs of the Radiological and Pathological Departments, and last but not least to Dr. C. Leonard Williams, medical officer of health for Barking, for much assistance throughout.

YORKSHIRE REFRACTION HOSPITAL. — This institution is at present housed in temporary premises in Leeds owing to the difficulty of obtaining a more suitable building, but the Yorkshire Optical Society is now hoping to raise £30,000 for the erection of its own hospital. It has been equipped and maintained hitherto at the cost of medical men and opticians. The professional staff is unpaid, and at present the hospital is open one afternoon and five evenings a week, which does not meet the demand.

SHEEP-DIPPING AND THE SHEPHERD.

By I. WALKER HALL, M.D. Vict.,
PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF BRISTOL;
AND
ROWLAND H. ELLIS, F.I.C.,
COUNTY ANALYST FOR GLOUCESTERSHIRE.

SHEEP-DIPPING is a compulsory procedure, and practitioners in rural areas are acquainted with abdominal, cutaneous, and nerve troubles that have been attributed to the absorption of arsenic during the process. In the case we are now recording the symptoms were suggestive of arsenical or ptomaine poisoning and the medical attendant did not feel justified in giving a death certificate. We were asked to carry out the pathological and chemical investigations, and our findings may be found useful for future reference.

The sheep dips in common use are generally made up in the form of a powder containing about 20 per cent. of arsenious oxide, mixed with sodium carbonate and finely ground sulphur. When prepared according to the directions, the dipping solutions contain 0·2 per cent. of soluble arsenic. It is, however, said to be a solution of arsenic trioxide in sodium di-hydrogen arsenate, and its toxicity to be about one-half of what it would be were the arsenic trioxide dissolved without the addition of an alkali.

The actual details of the sheep-dipping vary in different parts. The conditions under which the deceased man was reported to have worked were as follows. When 500 sheep were to be dipped, 35 two-pound packets of sheep dip were obtained from the estate office stores. The ends of these were slashed open with a knife. The contents of three packets were emptied into a two-gallon bucket; water was added and the powder and lumps dissolved with the aid of a stick. The mixture was then tipped into a 200-gallon bath. The procedure was repeated until the necessary density of the bath was attained. As each packet was emptied it was placed on the ground. When a heap of packets had collected they were burned. One man drove the sheep through a trap-hurdle into the bath; another guided their way through the bath to its exit by means of pronged sticks. The dripping sheep drained off for half an hour in one pen, and were then transferred to another pen for further drying. If the day was hot the sheep dried off in 2–4 hours; if it was dull and showery 8–24 hours were required. The dried sulphur-arsenic solution could be seen and felt on the sheep for several days. At the close of the day's dipping, the arsenical bath was left overnight, and later made up again to the required volume and strength by the addition of more "dip" powder. If the bath was not wanted again the residue was washed out into drains. When the dip solution was first prepared a yellow scum appeared on the surface. This was removed by a broom. The broom, after use, was swilled out and left by the bath for future use. None of the men wore overalls, gloves, or special garments. There were no printed instructions about the precautions the men should take in order to protect themselves from the solution, but they were told individually not to allow any of the fluid to get on to any sores or into their mouths. They were enjoined to wash their hands before eating. Water was provided for the purpose, but there was neither soap, nailbrush, nor towel.

At this farm there was a man, aged 48, who had been a shepherd since boyhood. On June 27th, 1929, he and one helper dipped 125 sheep. The bath had been prepared for him by the farm bailiff. The dipping of the sheep took one hour. On July 14th he got up early to look after his sheep and had for breakfast some fried beef prepared from some ribs of beef supplied the previous day. The remainder of the beef was then put aside in a wooden cupboard in the wooden hut he lived in, until Tuesday, July 16th, when it was "stewed up," and later eaten by other members of the household. In addition a part of a rib was given to one of his dogs.

The outside shade temperature during the days was as follows:—

	Maximal.	Minimal.
July 11th–12th	75° F.	62° F.
,, 12th–13th	78° F.	55° F.
,, 13th–14th	82° F.	59° F.
,, 14th–15th	84° F.	61° F.

The man had dinner with the family on July 14th, and they all had steak and kidney pudding. On Monday, July 15th, he could not go to work, owing to afebrile sickness and diarrhœa. This continued until the 17th, when his medical attendant was sent for. The doctor failed to find any outstanding signs on physical examination, and naturally regarded the case as ordinary summer diarrhœa. The next day, however, there were indications of cardiac collapse, and the man died on July 18th at 7.30 P.M. Meanwhile the dog appeared to be very ill, and it died at noon on the same day. It was promptly buried. None of the other members of the family was affected.

Autopsy.

Under the circumstances the coroner was informed. He ordered a post-mortem examination. This was carried out 15 hours after death. The chief findings were as follows: There were no rashes, but there were eight small pustular areas on the lower limbs. The stomach, duodenum, and jejunum showed widespread redness and swelling, with numerous small hæmorrhages. There were no ulcers. The lymphoid areas were swollen generally, but the lymph glands were not much enlarged. The ileum and colon were slightly red and swollen. The liver was not enlarged or fibrosed; it presented early fatty changes. Except for intense congestion the other organs were free from naked-eye morbid changes.

Microscopical Appearances.

The stomach and small intestines showed catarrh and small hæmorrhages. The liver was hyperæmic. Fatty changes were widespread, but the central zone of the lobules was not atrophic or fatty. The veins were distended, but there was not any evidence of chronic vascular damage. Interstitial tissues were not increased. The sinusoids were dilated generally, and contained many polynuclears and monocytes. Kupfer's cells were certainly swollen, but they were free from fatty metamorphoses. There were no signs of biliary obstruction or of jaundice. The heart did not present the features associated with fatty degeneration. The blood-vessels were congested, but there were no small hæmorrhages. The myocardial cells showed cloudy swelling, but the striæ were still easily demonstrated. The interstitial tissue was normal. The kidneys presented early post-mortem changes, but there was no change in the circulatory or interstitial tissues. The cerebral vessels were free from hæmorrhages, from perivascular infiltrations, and from atheroma. There were early calcification changes in the choroid plexus. The nerve-cells and axons were normal. The skin abscesses were staphylococcal in type. The blood became "putrid" in three days.

Numerous loopfuls of the contents of duodenum, jejunum, colon, and spleen were transferred to tubes of lactose broth. Twenty-four hours later all the non-lactose fermenters were isolated on selective media. From each of the areas mentioned there was isolated a bacillus which satisfied all the cultural criteria necessary for its identification as *aertrycke*. In addition, it agglutinated to the full titre of an *aertrycke* serum, failed to agglutinate with a paratyphoid B serum, and absorbed fully the agglutinins from the *aertrycke* serum.

The Dog.

After the dog had been buried for 36 hours it was exhumed. Putrefactive changes were well advanced, and histological features were indistinct. Gross pneumonic and abdominal, or traumatic changes could, however, be excluded. In spite of the general distribution of proteolytic and gas-forming bacteria, an attempt was made to isolate pathogenic organisms. Cultures were made as in the case of the man. An organism was ultimately isolated from the spleen and intestines which gave identical reactions to those of the strain obtained from the organs of the deceased man, and according to its serology was identified as an *aertrycke* bacillus.

Chemistry.

The tissues of both man and dog were examined for the presence of arsenic with the following results:—

The figures were obtained from the averaged materials. Previous experience had shown that with organs such as liver and kidney a total content could not be calculated from the results of the analysis of one portion. It was deemed necessary to use the whole organ or to take pieces from several parts of the organ and mince and mix them thoroughly. All the estimations were made by Marsh and electrolytic Marsh methods.

Shepherd.	Arsenic tri-oxide.	Shepherd.	Arsenic tri-oxide.
Stomach contents	None.	Kidneys	0·053 gr.
Stomach wall	None.	Brain	Trace.
Small intestine	None.	Spleen	Trace.
Small intestinal wall	None.	Sternum and ribs	None.
Large intestine contents	0·009 gr. in 87 g.	Pubic, thoracic, and scalp hair	None.
Large intestinal wall	0·011 gr. in 686 g.	Skin from abdomen	None.
Liver	0·148 gr.	Nail from toe	None.
Lungs	0·005 gr.	Urine (bladder empty).	
Heart	0·002 gr.		

gr. = grains; g. = grammes.

Dog.—Contents of liver: No arsenic tri-oxide.

The history of the case showed that there was access to sheep dip arsenic about 20 days before death. Detailed inquiry into the man's habits yielded negative results as to intake from other sources, and fish formed a negligible fraction of the household dietary. The absence of arsenic from the stomach and small intestines may be ascribed to the vomiting and diarrhœa of the early days of the illness. But, on the other hand, the arsenic contents of the thoroughly cleaned wall of the alimentary tract and that of the colon suggest excretion following absorption. The negative findings in bone, hair (from head, thorax, and pubis), nails and skin, are somewhat against a repeated or chronic intoxication. Yet if it is assumed that only one dose was taken, the major portion of the arsenic should have been excreted within 20 days." The general blood stream, according to the arsenic contents of brain, lungs, spleen, was carrying a minute amount. If a similar quantity had been carried daily for 20 days it would constitute a considerable addition to the hepatic residue, and point to the probability of an original intake not far short of a minimal human toxic dose. The morbid anatomy of the organs supports this inference. While the metal had caused a certain amount of hepatic damage, it had not broken down entirely its antitoxic capacity, for the arsenic had been transmitted to the general circulation only in small instalments. Its concentration in the blood stream was apparently insufficient to damage the walls of the smaller vessels or to effect a necrosis of the parenchyma of the vital organs. The cardiac and nerve-cells were practically unaltered. The picture was entirely different from the poisonings where the liver has been so damaged that the entering arsenic fails to be arrested and passes almost unrestrained to the systemic vessels and cells.

It may be that the condition of the liver is the factor which finally determines the distribution of arsenic in the outlying tissues, and that the finding of the metal in the skeletal and epidermal areas is a measure of the damaged hepatic functions. When the liver similarly ceases to protect the myocardial cells, then there must enter a further factor—viz., that of slowed circulation, first peripheral and later central. The elimination of the arsenic is then lessened and delayed, and organs other than liver tend to store increasing amounts of the metal. In this case the circulatory organs were normal up to five days before death. Heart failure became evident only about ten hours before death. Hence it would be impossible that there would be any perceptible hold-up of the arsenic from progressive stasis.

Had the fatal *aertrycke* infection not intervened it is possible that the residue of the arsenic might have been eliminated in time and the hepatic damage have been compensated. In such a case an examination at a later date might have yielded negative results. Clinically, the arsenical intake did not give rise to any symptoms, and it was not possible to obtain any previous history of arsenical action. As, however, it seems probable that arsenic was ingested during the last sheep-dipping, it is very likely that similar intakes had happened before. Taking into consideration the quantity of arsenic in the tissues it is permissible to assume, perhaps, that the original dose would have caused severe damage in a susceptible individual, and that even in those less sensitive it would call for the assumption of some degree of acquired tolerance. Tolerance for arsenic implies lessened susceptibility or insusceptibility of the tissue cells for arsenic. It is manifested, presumably, by minimal damage to liver and other "affinity" cells and elimination by the most direct routes. In this instance the wall of the large intestine and the kidney formed the chief, if not the only pathways. Further, the cardiac and renal tissues did not show the usual "arsenical" toxic changes. They were apparently protected by the liver cells, which themselves suffered but slightly. In addition, the blood content in the spleen was slight, while the bones and the skin and the hair were arsenic-free, although excretion of arsenic was being carried on by other channels. Histologically, the blood apparatus did not show any signs of chronic passive hyperæmia, and capillary hæmorrhages were not present in heart or brain.

Table showing Arsenic Output and Action in a "Sensitised" Individual.

Days.	Time.	Arsenic intake, grains.	Urine: Arsenic output, grains.	Clinical.
1.	9·30 A.M.	0·1802	—	—
	10·30 A.M.	—	None.	—
	12 noon.	—	0·004	—
	4 P.M.	—	0·0046	—
	10 P.M.	—	0·0034	—
2.	9 A.M.	0·1802	—	—
	7 A.M.	—	0·0030	—
	8 P.M.	—	0·0215	—
3.	8 A.M.	—	0·0119	Slight nausea.
	9.30 A.M.	0·1802	—	—
4.	9.30 A.M.	0·1802	0·0275	Headache; nausea; loss of control of legs.
5.	—	—	0·0283*	Burning sensation in throat.
6.	—	—	0·0624	Warmth and sense of fullness in chest and abdomen.
7.	—	—	0·0297	Nausea and burning absent. Diarrhœa present.
8.	—	—	0·0192	Diarrhœa.
9.	—	—	0·0129	Severe pains right foot and knee.
10.	—	—	0·0125	Twinges in left knee and forearm.
11.	—	—	0·0122	"Steppage" gait.
12.	—	—	0·0028	—
13.	—	—	0·0012	—
14.	—	—	0·0012	Gradual decrease of neuritic symptoms.
15.	—	—	0·00018	—
16.	—	—	0·00058	—
17.	—	—	0·00097	—
18.	—	—	0·00009	—

* Twelve hours' urine only. On the average for 24 hours, the quantity should be over 0·0400 grains.

Arsenic Contents of Hair from a "Sensitised" Patient.

Oct. 7th. Hair cut. No arsenic.
Oct. 8th–12th. Arsenic intake 0·72 grains.
Nov. 12th: Hair contained 0·005 } Mg. of arsenic per gramme of hair.
Dec. 17th: „ „ 0·0004 }

These findings, therefore, raise the question whether tolerance lies in a developed cellular anti-affinity and its absence in the permeability of capillaries extending later to an actual damage. It is beyond a doubt that in cases of homicidal or experimental arsenic poisoning, or even during arsenical medication, the skin and hair may contain considerable quantities of the metal. It seems as if in this case the absence of arsenic from its usual seats may properly be ascribed to a tolerance. The salmonella infection which terminated the case may have hastened slightly the excretion of arsenic by the associated active hyperæmia and, crosswise, its course may have been accelerated owing to the absence of a vigorous defence. The death of the dog from the same infection, and apparently within a shorter period, rather suggests, however, that the infection was too massive to be affected by any slight alteration in resistance.

An opportune case of arsenical hypersensitiveness suggested some further considerations.

A patient who had suffered from psoriasis for many years was accustomed to take gr. 0·27 of arsenic with impunity. His last attack and last dose of arsenic was in 1926. He was now given gr. 0·18 of arsenic for four consecutive days. Symptoms of nausea appeared on the third day; pharyngeal irritation was evident on the fifth day; diarrhœa occurred on the seventh day; and neuritis on the ninth day. Arsenic was voided in the urine passed two and a half hours after the first dose. The output gradually increased up to the sixth day. The day excretion varied but slightly from that of the night. From the 6th to the 12th day there was a gradual fall, and then a sudden decrease. On the 18th day the urine was practically arsenic-free, although the arsenic contents of the hair on the 35th and 70th days point to a continuous circulation and elimination of minute amounts. About 36 per cent. of the total intake of arsenic was voided in the urine during 18 days, the larger proportion being excreted during the first 11 days.

The presence of arsenic in the urine so soon as two and a half hours after ingestion, and the early onset of mucosal and nerve manifestations without serious damage to heart, liver, and kidney, suggest a rapid passage through the liver, and an increased permeability of the general capillaries. It may be that the susceptibility towards arsenic is mainly a question of endothelial "allergic" changes, and that tolerance is the expression of specialised endothelial selectivity.

Summary.

1. The death of a shepherd was preceded by symptoms indistinguishable from arsenical poisoning. Considerable amounts of arsenic were found post mortem in various organs. Elimination was proceeding via the kidney and the wall of the large intestine, but not by skin and hair. 2. Death was proved to be due to an infection by *aertrycke* bacilli. One of the shepherd's dogs died from the same cause. 3. It is suggested that, through the ease of occupational intake of arsenic, a tolerance had been established. Such tolerance seems to be associated with certain histological appearances and a distribution of arsenic differing from those of homicidal poisoning. 4. The supervision of those engaged in handling commercial solutions of arsenic might be more precise. Workers vary in their susceptibility to arsenic, and a dosage which may evoke tolerance in one individual may damage another permanently.

HOSPITAL COSTS.—In Wrexham War Memorial Hospital last year the average number of beds in daily occupation was 91·75, and the average cost per occupied bed was £131 7*s.* 9*d.*, a reduction of 1*s.* 7*d.* Each in-patient cost £9 4*s.* 10*d.*, a fall of 13*s.* 6*d.*, and each out-patient (5431) 6*s.* 0¾*d.*—Acton (Middlesex) Hospital received 1186 in-patients who stayed an average of 13·88 days each, and their weekly cost was £3 5*s.* 1*d.*, an increase of 2*s.* 2*d.* on the preceding year.—At the Royal Devon and Exeter Hospital the cost per occupied bed (3481 in-patients) was £128 4*s.* 10*d.*, an increase of 7*s.* 10*d.*

SUSSEX PROVIDENT SCHEME.—In the first year of this scheme (1921) the sum of £332 was distributed among the various hospitals and authorities coöperating with it. In 1929 the figure was over £13,000. A new feature of the scheme is the inclusion of the Queen's nurses. Owing to the overcrowded state of all hospitals, patients are discharged as soon as possible, but many still require dressings, and under the new arrangement these can now be done by the Queen's nurses in the homes of the patients. The subscription for this is but an extra 2*s.* 6*d.*, and to show how welcome it is over 700 subscribers have already joined this section.

Clinical and Laboratory Notes.

THE DURATION OF YELLOW FEVER IMMUNITY.

By Edward Hindle, Sc.D. Camb.,
BEIT MEMORIAL FELLOW IN TROPICAL MEDICINE.
(From the Wellcome Bureau of Scientific Research.)

It is well known that recovery from an attack of yellow fever is followed by the development of a high degree of immunity, and it has generally been assumed that this immunity is of long duration, since cases of reinfection are extremely rare, but hitherto very few direct experiments bearing on this subject seem to have been recorded.

Theiler and Sellards,[1] in 1928, tested the protective value of convalescent serum collected in Brazil about three and a half months after an attack, and subsequently stored for about two years in the ice-chest, and found that the sera of seven out of nine patients protected monkeys against infection with an African strain of the virus. Hudson, Philip, and Davis[2] last year recorded similar experiments also made principally with the object of showing the identity of the Brazilian and African strains of yellow fever. Their results indicate considerable variations in the degree of protection conferred on monkeys by the inoculation of convalescent serum from different individuals. The sera of eleven patients who had recovered from the disease in West Africa, when inoculated into rhesus monkeys, protected them against lethal doses of a West African virus, but in every case less than two years had elapsed between the attack of fever and the date when the blood was collected. When longer periods had elapsed, as in the case of sera from South American patients, in some instances the protective value seems to have disappeared. The serum of Case 5, whose blood was collected approximately nine years after the attack, failed to protect monkeys in doses of 1·0 c.cm., and 0·1 c.cm. respectively; whilst the serum of Case 6, with a seven years' interval, protected in doses of 1·5 c.cm and 1·0 c.cm. respectively, whilst 0·1 c.cm. failed to protect. When sera of comparatively recent cases were tested effective passive immunity was conferred on monkeys against lethal doses of the virus.

It will be seen that the results of these experiments suggest that immunity may gradually disappear, but it should be noted that these sera had been collected in Brazil and subsequently transported to West Africa, so that considerable periods had elapsed before they were tested, during which they were exposed to varying conditions (e.g., temperature).

Through the kindness of Dr. A. Breinl, I have recently had the opportunity of testing his blood. He suffered from a severe attack of yellow fever in Manáos, Brazil, during 1905, since when he has never visited any regions where the disease is endemic. Four c.cm. of his citrated blood were mixed with 0·05 g. of the liver of a yellow fever monkey infected with an African strain of the virus, and also with 0·5 c.cm. of the blood of another infected monkey collected on the second day of fever. This second monkey was infected with a Brazilian strain of yellow fever. The mixture was at once inoculated intraperitoneally into a rhesus monkey. This animal showed no rise in temperature or any other signs of infection, whilst a control animal inoculated with 0·05 g. of the infected liver used in the experiment died of yellow fever four and a half days later. The experiment was repeated with a second monkey, which received an injection of 1 c.cm. of the patient's blood and immediately afterwards 0·05 g. of liver of a *monkey infected with an African strain of the* virus. This second monkey also showed no signs of infection.

The results show that immunity following an attack of yellow fever may persist for at least 24 years, and that after this period the blood is still capable of producing passive immunity in monkeys. Moreover, the blood protected monkeys against both African and Brazilian strains of yellow fever. The results of this experiment, therefore, confirm the generally accepted view that recovery from yellow fever is followed by a lasting immunity, and also furnish additional evidence as to the identity of the West African and Brazilian strains of this disease.

A CASE OF GLUTEAL ANEURYSM.

By A. D. Charters, M.B. Camb., D.T.M. & H. Eng.,
ASSISTANT PHYSICIAN AND SURGEON TO THE FREDA-CARR HOSPITAL (C.M.S.), NGORA, UGANDA, AFRICA.

A man, aged about 45, a native of the Teso tribe, complained of pain and swelling in the right buttock. He was admitted to the Freda-Carr Hospital on Oct. 11th, 1929.

He had four wives and ten children, four by one wife and six by another. None of his wives had had any miscarriages. One of his children died at the age of 15 years, all the rest being still alive and healthy. He stated that he had had syphilis when a small boy, by which he meant that he had developed a rash on his trunk and arms without involvement of his penis. Apart from this he had always been in good health. He had never had any ulcers or sores anywhere on his body, and no history of injury to his buttock could be elicited. He stated that his symptoms started one month before admission, when he had begun to notice slight swelling and pain in his right buttock. The swelling rapidly increased in size, and the pain, which was continuous in character and radiated down the back of his right leg, became more severe.

Examination in Hospital.

He was a tall, thin man, and had a temperature of 99·6° F. The walls of his arteries were somewhat thickened. There was no enlargement of his heart, and I could find nothing abnormal on examination of his cardiac and respiratory systems. His urine contained no albumin or sugar. His knee-jerks and ankle-jerks were normal, and his pupils reacted to light and accommodation. There were no ulcers or scars over his tibiæ or other signs of syphilis. The whole of his right buttock was enormously swollen, and a heaving pulsation, expansile in character and involving the whole buttock, could be both seen and felt. The tumour was tense, tender, and incompressible, and deep fluctuation could be readily elicited. A marked systolic thrill could be felt by the hand half an inch behind the tip of the great trochanter. On auscultation a loud, harsh, systolic bruit was heard all over the buttock, most marked at a point half an inch behind the tip of the great trochanter. Firm pressure on the abdomen at the junction of the upper and middle thirds of a line drawn from a point half an inch below and to the left of the umbilicus to a point midway between the anterior superior iliac spine and the symphysis pubis on the right side—i.e., over the origin of the right internal iliac artery—obliterated the pulsation and systolic bruit in the tumour. Pressure over the common femoral artery had no effect. The enormous size of the tumour can be gathered from a study of the following measurements:—

	R. ins.	L. ins.
Anterior superior iliac spine to ischial tuberosity	15	12
Iliac tubercle to ischial tuberosity	16	11
Posterior superior iliac spine to ischial tuberosity	12	8¼
Outer margin of anus to tip of great trochanter	12	8¼

R. and L. = Right side and left side; ins. = inches.

I inserted a fine needle into the tumour. It was felt to pass through a hard outer wall, after which a sudden diminution of resistance occurred. The syringe filled with blood, the pressure within the tumour rapidly forcing up the piston. A firm bandage was applied, the foot of the bed raised, and the patient cautioned not to move.

Operation.

A diagnosis of aneurysm of the sciatic artery was made owing to the position of the thrill and maximum bruit. I considered that it would be quite impossible to ligature this artery, the enormous size of the aneurysm rendering puncture inevitable, and decided to ligature the right internal iliac artery.

On the following day, Oct. 12th, the patient was writhing with pain and begged for the operation. The swelling had still further increased in size and was more prominent. The skin over the tumour was shiny and, as the aneurysm was obviously on the point of bursting, the preparation of the operating theatre was hastened. The bladder was emptied by a catheter. An anæsthetic of chloroform and ether was administered, and the patient placed in the Trendelenburg position. A mid-line incision was made from the umbilicus to a point about one inch above the symphysis pubis, the two recti were separated, and the peritoneal cavity was opened. Obliteration of the pulsation and systolic bruit in the aneurysm by pressure of a finger on the right internal iliac artery was confirmed. While an assistant confined the intestines and great omentum to the upper part of the abdomen by means of a strip of gauze, the posterior parietal peritoneum over the artery was carefully divided for a distance of one inch, and the cut edges dissected up on each side. The right ureter having been dissected away from the anterior surface of the artery, the sheath of the latter was picked up with dissecting forceps and incised with a scalpel. The artery was then ligatured according to the method which Prof. A. W. Sheen prefers for occlusion of the innominate artery. Two strands of stout silk were passed beneath the vessel at a distance of about half an inch from each other, the aneurysm needle being passed from the medial to the lateral side inside the arterial sheath. The first turn of a reef-knot was tied in the proximal strand, and tightened until pulsation had ceased in the artery beyond. The distal strand was then completely tied by a reef-knot, and finally the second turn of the proximal ligature completed. The posterior parietal peritoneum was sutured over the artery with a continuous catgut suture, and finally the anterior abdominal wall closed in the usual way.

For two days after the operation the patient appeared to be progressing favourably, but on the third day, Oct. 15th, he suddenly developed the symptoms and signs of acute dilatation of the stomach. He vomited profuse quantities of bile-stained watery fluid at frequent intervals, on one occasion bringing up about half a gallon of liquid, and became extremely thirsty. He was most comfortable when lying on his left side. His temperature was 97° F. and his pulse became very rapid and weak. The epigastric region was visibly pushed forward by the distended stomach and was tympanitic on percussion. No peristalsis was visible and there was no rigidity of the abdomen. All food and water were immediately forbidden for 42 hours, a special attendant being placed on night duty to see that nothing was taken by mouth. At 11.30 A.M. pituitary extract 0·5 c.cm. was injected subcutaneously and a drachm of sodium bicarbonate in an ounce of water was given by mouth. At 4 P.M. a subcutaneous infusion of 16 oz. of normal saline was given in two portions into the left flank and right axilla respectively. The pulse was only just perceptible, though owing to its thickened wall the radial artery could be easily rolled under the finger. Vomiting and hiccup were very troublesome, and the brow was covered with a cold sweat. At 6 P.M. camphor gr. 1 in olive oil ♏ v. followed by ½ c.cm. of pituitary extract were injected without producing any recognisable change in the patient's condition. An intravenous infusion of 14 oz. of normal saline containing 6 per cent. of gum arabic was administered, and was followed by a slight though definite improvement in the pulse, which, however, was still barely perceptible.

On Oct. 16th we were surprised to see the patient still alive. His pulse was about the same. He was still vomiting though not bringing up such large quantities of fluid. He still had a distressing hiccup, and complained of great thirst. At 9.30 A.M. 10 oz. of the gum saline were given intravenously, and were followed by a very marked and permanent improvement in the pulse. Vomiting ceased and did not again recur. Strychnine hydrochloride gr. 1/30 was injected hypodermically. At 11.30 A.M. 10 oz. of 7 per cent. glucose in normal saline were introduced into the rectum and retained. A mixture containing 1 dr. of bismuth oxycarbonate, 20 gr. of sodium bicarbonate, and 1 oz. of water was ordered three times a day. At 3.30 P.M. another intravenous infusion of 18 oz. of gum saline was administered with great benefit to the patient, the pulse being almost normal in character. At 6 P.M. 10 oz. of 7 per cent. glucose in saline were given rectally.

On Oct. 17th he no longer complained of hiccup, and his pulse was normal. It was decided to allow his small quantities of fluid by mouth, and he was therefore given 2 oz. of equal parts of milk and water every two hours. On the 18th he took milk, soup, jellies, custard, and rice in small quantities every three hours. On the 19th he was allowed normal diet.

Immediately after the operation all pain and tenderness in the buttock had markedly diminished and by the third day, Oct. 15th, had almost disappeared.

On Oct. 19th he complained of no discomfort, nor was there any tenderness on palpation. The aneurysm was no longer tense, and the shiny appearance of the skin had vanished. The buttocks were flabbier on palpation, but fluctuation could still be elicited.

On Oct. 21st a comparative measurement of the two gluteal regions was as follows:—

	R. ins.	L. ins.
Anterior superior iliac spine to ischial tuberosity	12	11½
Iliac tubercle to ischial tuberosity	14	11
Posterior superior iliac spine to ischial tuberosity	9	8
Outer margin of anus to tip of great trochanter	11½	8½

On Oct. 20th a needle was inserted into the aneurysm. No fluid could be aspirated, but a few small particles of clotted blood were drawn into the syringe. On the 28th the right buttock appeared quite normal on palpation, except for slight hardness over an area half an inch in diameter just behind the tip of the great trochanter. On Nov. 1st, 19 days after the operation, the two buttocks appeared to be similar in size, and an examination of the right side revealed no trace of any hardness or other abnormality. A month later, on Dec. 2nd, an examination revealed the following measurements:—

	R. ins.	L. ins.
Anterior superior iliac spine to ischial tuberosity	10½	11
Iliac tubercle to ischial tuberosity	10	10½
Posterior superior iliac spine to ischial tuberosity	7½	8
Outer margin of anus to tip of great trochanter	8	8½

There was wasting of the right gluteal muscles, thus accounting for the smaller dimensions on this side. Apart from the fact that the patient developed a lobar pneumonia of a mild type involving the base of his left lung, which began on Oct. 26th and terminated by lysis, and that the abdominal incision was slow in uniting—presumably owing to deficient vitality of the tissues, but it had completely closed by Dec. 4th—there were no other complications. He was discharged on the 9th in a perfectly healthy condition.

The interesting points about this case are as follows:

1. The enormous size of the aneurysm and its rapid cure by ligature of the internal iliac artery, though undoubtedly the sluggish circulation which accompanied his gastric condition contributed towards the coagulation of blood.

2. The markedly beneficial effect on the acute dilatation of his stomach of a combintaion of intravenous gum saline infusions with the restriction of all food and fluid by mouth.

I should like to thank Dr. E. V. Hunter, who gave the anæsthetic for the operation and administered the intravenous infusions, for his valuable advice with regard to this case.

LOBAR PNEUMONIA ASSOCIATED WITH OLD MALUNITED FRACTURE OF RIBS.

By H. A. Dunlop, M.B., M.R.C.P. Lond.,
MEDICAL REGISTRAR, WESTMINSTER HOSPITAL;
AND
M. Kokia, M.R.C.S. Eng.,
HOUSE PHYSICIAN TO THE HOSPITAL.

A BOOTMAKER, aged 58, walked into Westminster Hospital on Dec. 31st, 1929, complaining of breathlessness and swelling of the feet.

The dyspnœa was an old symptom, for the patient could not recall a time when he had been free from it, but during the three weeks immediately before admission it had been markedly aggravated. The swelling of the feet was of three weeks' duration. There was a slight cough, but no pain in the chest; nor had there ever been hæmoptysis. The patient had for a long time drunk heavily. No history of antecedent lues or rheumatism was elicited.

The patient was obese, cyanosed, and extremely dyspnœic. He was conscious, but somewhat confused and difficult to interrogate. The temperature was 95° F., the pulse-rate

76 per minute, and the respirations 30 per minute, deep in character, and laboured. The pulse was feeble, but of less volume in the right upper limb than in the left. The blood pressure was 100/40 mm. Hg in each arm. The heart sounds were inaudible. The right side of the chest, especially the upper part, was much flattened and almost immobile. There was dullness over the whole of the right lung, where also the breath sounds were very feeble. Adventitious sounds—rhonchi and bubbling râles—were heard over both lungs. The left side of the chest was hyper-resonant, and the superficial cardiac dullness much diminished. The abdomen was distended; there was no shifting dullness or fluid thrill. The liver was not felt. The ankles were œdematous. The small quantity of urine passed contained much albumin.

The diagnosis was one of heart failure complicating some lesion of the right lung. The flattening of the chest suggested an old lesion, but the absence of chronic cough or sputum seemed to make this unlikely. The sputum was free from tubercle bacilli.

The man died from cardiac failure 36 hours after admission.

Post-mortem Appearances.—The flattening of the chest was seen to be due to old malunited fracture of the right upper ribs from the second to the sixth inclusive. There was no bony union between adjacent ribs, but the inner aspect of the thoracic wall was the seat of a dense mass of fibrous tissue extending into the root of the neck. The subclavian artery was entangled in and compressed by this massive cicatrix, and its lumen much diminished. The ribs were impalpable from without on account of the thick subcutaneous tissue. The right lung showed lobar pneumonia. The upper and middle lobes were in a condition of red hepatisation, the lower lobe being moderately congested and œdematous. The left lung was emphysematous and œdematous. The heart was dilated and fatty. The liver was congested, fatty, and cirrhotic. The kidneys were of the "beer-drinker's" type. There was a little free fluid in the peritoneal cavity. The ankles were œdematous.

This case is evidently one of chronic alcoholic poisoning with gross cardiac, hepatic, and renal damage, in which a terminal lobar pneumonia occurred. The chief point of interest is whether the interference with the expansion of the right lung, caused by the old injury to the ribs, favoured the development of pneumonia at that particular site.

We are indebted to Sir James Purves-Stewart for permission to publish the clinical notes, and to Dr. J. A. Braxton Hicks for the post-mortem findings.

DONATIONS AND BEQUESTS.—Mr. William John Checkley, of Lindfield-gardens, Hampstead, left £1000 each to the Middlesex Hospital (for cancer research) and the Home for Incurables, Putney, and £500 each to the Brompton Hospital for Consumption and the National Hospital for the Paralysed and Epileptic.—Mr. John Dickinson Eaton, of Kenwood, Park-road, Sheffield, besides bequests for other charitable purposes, left £1000 each to the Sheffield Royal Infirmary, the Sheffield Royal Hospital, the Derby Infirmary, and the Rotherham Infirmary, and £500 each to the Ilkeston Hospital, the Jessop Hospital for Women, and the Sheffield Children's Hospital.—By the will of Mr. F. H. Lambert, of Penarth, Glamorgan, who left a fortune of £248,140, with net personalty of £244,771, the testator, after gifts to his secretary and servants, left the residue of the property in trust for his wife for life, and on her death one-fourth to the Free Trade Union, and one-fourth equally between the Salvation Army, Coal Trades Benevolent Association, King Edward VII. Hospital, Cardiff, Cardiff Institution for the Blind, Royal Merchant Seamen's Orphanage, the National Institution for the Blind, Great Portland-street, London, the Salvation Army Maternity Home, Cardiff, the British Home for Incurables, and the Women's Metropole or Hotel in Cardiff (of which Miss Swain is the present superintendent).—Among other bequests Miss Frances Ripley, of Leeds, left £1000 each to the Leeds General Infirmary, the Leeds Public Dispensary, St. Dunstan's Hostel for Blinded Sailors and Soldiers; £500 each to the Leeds Hospital for Women and Children, the Leeds Incorporated Institution for the Blind, Deaf, and Dumb, and the Leeds branch of Dr. Barnardo's Homes.—By the will of Mr. Francis Almond Hocking, pharmacist to the London Hospital, the testator left his microscope to the London Hospital, Whitechapel, and subject to two life interests, 750 guineas upon trust to establish one or more annual prizes for competition among students of the London Hospital Medical College.

Medical Societies.

THE BRITISH INSTITUTE OF RADIOLOGY.

AT a meeting held at this Institute on Feb. 20th the chair was taken by Dr. L. A. ROWDEN, and Dr. A. E. BARCLAY read a paper on

THE MECHANISM OF SWALLOWING.

An analysis of the movements seen on the X ray screen, he said, showed that many of the current ideas about the mechanics of swallowing needed revision. When food was swallowed the whole larynx, with the trachea, rose; the pharyngeal space was obliterated for a fraction of a second and the mass of food was thrown back by the action of the tongue and dropped through the pharynx and for some distance down the œsophagus as if there were no walls there at all. Not until it reached the level of the clavicle did it seem to be imprisoned in any way, or show any indication of peristalsis. To analyse the process, a fluid was useless, as it passed too quickly, and a very thick food induced a gymnastic type of swallowing; therefore food with a normal consistency should be used. Both nose and mouth must be closed for swallowing. If the lips were open the mouth was sealed off by the tongue fitting the roof, while the soft palate sealed off the nasopharynx. At the same time the larynx was drawn up about half an inch and the tongue pressed still more forcibly against the hard palate, from the tip progressively backwards, forcing the food back into the pharynx. When once the bolus had actually left the tongue there was little, if any, sign in the X ray of any muscular action propelling the mass from behind. It gave the impression rather of being sucked down, a very different appearance from that, for instance, of the passage of food through the small intestine or lower œsophagus. The rapidity of the passage through the pharynx was extraordinary; it took perhaps an eighth of a second to pass from soft palate to behind the larynx. The same type of food squirted into a glass or rubber tube would slide down very slowly. There therefore seemed to be some suction action at work.

To account for this appearance the speaker had studied many subjects, either swallowing opaque food or insufflated with bismuth and lycopodium. He had found that the pharynx was completely emptied of air and became a potential space for just a fraction of a second before swallowing. As the hyoid rose the tongue slipped down inside it and pressed into the upper larynx, obliterating it right down to the false vocal cords, while the epiglottis was pressed vertically against the back of the pharynx. At the same time the mouth of the œsophagus was pulled right up behind the larynx and into contact with the epiglottis, thus covering up the larynx from behind. The character of the mucous membrane of the parts confirmed this view of the mechanism. Parts that had to stand wear and pressure were lined by stratified squamous epithelium; this epithelium covered the upper part of the back of the epiglottis and the upper part of the aryteno-epiglottic folds, and these areas also had taste buds, suggesting that they were exposed to the food stream. A number of films also showed a streak of air in the œsophagus, suggesting that when it was pulled up it became an open-mouthed receptacle like a Christmas stocking. Apparently the upper larynx opened up again as the hyoid came down, while the œsophagus waited in its epiglottic position for the bolus to be popped in, just as the nestling holds up its open beak until the mother pops in the worm and then sinks back into the nest. When nasal mucus stuck just below the nasal pharynx efforts to swallow it seemed to have very little effect. On analysing the attempt it could be realised subjectively that it was not direct muscular action that was aimed at but the suction of swallowing, and this could not be increased beyond a certain point. There was very little voluntary power over mucus on the posterior wall of the pharynx and, as seen radiographically, food seldom touched the back of the pharynx. The act of swallowing began with the tongue and ended at the junction of the upper and middle thirds of the œsophagus where peristalsis appeared, where foreign bodies nearly always lodged, where the nerve-supply changed, where the muscle altered from voluntary to unstriated in type, and where the muscularis mucosæ became increasingly prominent.

Prof. J. PRESTON MAXWELL then read a paper on

Osteomalacia and Fœtal Rickets.

It seemed to be clear, he said, that true osteomalacia was the manifestation of rickets in bones that had reached maturity, and that it was connected with a shortage of vitamin D and in most cases with an actual calcium starvation. It must be distinguished from other diseases causing osteoporosis, such as hyperparathyroidism, pseudo-osteomalacia malignum, and in rare instances hyperthyroidism. It was a matter of doubt whether the so-called physiological osteomalacia of pregnancy (Hanau) was not a mild form of osteomalacia. In most cases the blood calcium was reduced to 5–8 mg. per 100 c.cm. of serum and the blood phosphorus to 1–2·5 mg. per 100 c.cm. Deformities might affect the chest, pelvis, or long bones or any two or all of these. Pure kyphosis was rare, but kypho-scoliosis was common. There was no actual destruction of bone, but the new bone laid down was osteoid. The ribs tended to become flattened, producing a modified form of pigeon-breast, and the sternum crumpled up so that the distance from the episternal notch to the ensiform cartilage might be reduced to two inches. The four characteristic deformities in the pelvis were yielding at the acetabulum and ilio-pubic junction, producing rostration of the pelvis; yielding at the ischio-pubic junction, resulting in the narrowing of the trans-ischial diameter, and a curious twisted crumpling of the ascending ramus of the ischium and descending ramus of the pubes; shortening of the sacral index, its anterior surface becoming much more concave and the coccyx being carried forward so as almost to block the pelvic outlet; and rolling of the crests of the ilia, so deepening the iliac fossæ. The general picture was triradiate. Irregular bending and transverse fractures were the two principal deformities of the long bones. Coxa vara was very common, and the clavicle might be bent almost double.

Radiology could distinguish well-marked cases of the different types of osteoporosis, but not the milder cases. It could also help in obstetrics in revealing the shape and size of the osteomalacic pelvis. The child did not escape the ill-effects of the mother's disease; it might be starved of calcium or be born with a tendency to rickets, or with actual antenatal rickets. Appropriate treatment for the mother would provide the necessary vitamin, calcium, and phosphorus for the child. Osteomalacia yielded to a sufficient supply of these substances, either in the form of irradiated ergosterol or of cod-liver oil, but preferably a combination of both. The patient must also have sunshine, or ultra-violet light, and exercise. The disease appeared in men as well as in women, and might be seen in the mild form at puberty or even after the menopause.

Discussion.

Dr. BARCLAY showed a slide illustrating rickets in an experimental rat; one hundred thousandth of a milligramme of vitamin D, he said, prevented this condition.

Dr. G. B. BUSH related the case of a lady who had complained of extraordinary mobility of the fœtus and of pains in the thighs. He had given cod-liver oil quite empirically, and the symptoms had disappeared. He asked how large the doses of cod-liver oil for osteomalacia should be.

Dr. MAURICE WEINBREN asked whether osteomalacia was caused by a general lack of ultra-violet light throughout the year or at certain periods of the year.

Dr. A. J. ILES asked if the lady mentioned by Prof. Maxwell had been living on rice.

Dr. RICHARD CONNELL asked if osteomalacia caused abortion, since certain manufacturers of cod-liver oil had advocated it as a remedy.

Prof. MAXWELL, replying, said that in an advanced case the daily dose of cod-liver oil was one and a half to two ounces. A milligramme of ergosterol with a teaspoonful of cod-liver oil gave better results. Most of the patients came from an altitude of 2500 ft., and belonged to the middle classes who could not afford proper diet and were too proud to work in the sun but lived in their houses in the dark. The lady had not been living on rice, and her husband, a medical man, had been giving her calcium, which was not being absorbed. Abortions did not appear to be more common in the osteomalacial region than anywhere else.

Dr. JOHN MUIR read a paper on

The Irritable Colon.

He first emphasised the fact that great caution must be exercised in the X ray observation of disordered function. In many patients vague dyspeptic symptoms were associated with colonic disorders. Treatment of the gastric trouble was but palliative, and purgative mixtures, though they gave temporary relief, finally aggravated the condition. The radiologist also knew a group of cases with gastric symptoms but no indication under X ray of any recognised lesion. A formula frequently used was: "the duodenum shows signs of irritation which may be due to local ulcer, but no direct evidence of such ulcer is detected, and appearances may be due to reflex irritation from gall-bladder, appendix, or colon." The X ray in these cases showed spasm in the pyloric vestibule, pylorus, or duodenal bulb. "Only spasm" might exclude organic lesion, but still demanded explanation. Gentle palpation to relax the pylorus might defeat its own ends by increasing the spasm, and the patient should be allowed to lie down and rest for a time. When duodenal ulceration had been excluded there remained a large group of cases in which pylorospasm was accompanied by a constantly changing spasm of the duodenal bulb—"the ghost bulb." If the patient were carefully observed and the proper technique used, the bulb would assume its normal shape from time to time, thus eliminating organic change. If there were a history of hæmorrhage and tenderness over the bulb the possibility of ulcer was still present, but in the absence of these signs the source of irritation must be sought elsewhere. The gall-bladder produced a typical kind of protracted spasm of the pyloric third of the stomach, so that it assumed a sausage shape, indented ever so slightly by each passing wave of peristalsis. If the gall-bladder could be excluded the appendix was all too often incriminated. It should not be accused in the absence of two out of three definite localising signs—viz., fixation, tenderness upon pressure over the visible appendix, and undoubted stasis in the end of the ileum. Kinks and irregular filling did not indicate an abnormal appendix. If the colon were at fault the tenderness was distributed along its course and often accentuated over the middle of the transverse colon or over the descending colon. Eighteen to twenty-four hours after an opaque meal the X ray would show irregular segmentation and sometimes stretches of narrowing with dilatation of the proximal part. An opaque enema showed this narrowing and was often seen to pass along a somewhat spastic pelvic colon and to shoot along a rigid narrowed descending colon in a very striking way. Both methods were needed for diagnosis, and in most cases screen observation was almost equally important. Great caution was required in the interpretation of colon shadows, for there was a very wide variation within the limits of the normal. An organic lesion showed permanent alteration; the irritable colon was characterised by great variability.

It seemed hopeless at present to correlate this radiological condition with any clinical entity. Most cases seemed to result from long-standing constipation or long-continued but ill-advised efforts to combat constipation.

Dr. G. E. **Vilvandré** thought that there was no connexion between duodenal ulcer and spasmodic contraction of the colon. Spasm might be seen in diverticulosis before diverticula appeared. Early carcinoma would also cause local irritability. Spasm was usually due to a local condition. Pylorospasm in the great majority of cases meant duodenal ulcer.

Dr. **Connell** pointed out the frequency with which neuroses attacked the pyloric and sigmoid regions. The sigmoid might be rigidly anchored to the brim of the pelvis by a mesentery, and might become irritable in conditions of overwork and worry. Considerable amount of irritability was normal after an enema, when the colon had been filled to its fullest capacity. The radiologist should be reluctant to diagnose small areas of irritability or spasticity as abnormal in the absence of any organic disease.

The **Chairman** thought that further investigation with opaque enemata might show that many cases of irritable colon were due to diverticulosis in a prediverticula stage.

Dr. F. E. **Lynham** spoke of the effect of massage in removing apparent spasm.

Dr. **Muir**, in reply, pointed out that he excluded all localised spasm and had dealt only with generalised irritability.

ROYAL SOCIETY OF MEDICINE.

SECTIONS OF OBSTETRICS AND ELECTROTHERAPEUTICS.

At a joint meeting of these Sections on Feb. 21st, with Mr. **Arthur Giles**, President of the Section of Obstetrics, in the chair, a discussion on the Position of

RADIUM IN THE TREATMENT OF GYNÆCOLOGICAL CONDITIONS

was opened by Mr. **Malcolm Donaldson**. Five or six years ago, he said, he had tried to interest the Obstetric Section in the treatment of carcinoma of the cervix uteri by radium. He had not only failed, but had been denounced as an enthusiast. Since that time the pendulum had swung to the opposite extreme. Radium had proved to be one of the most valuable of therapeutic agents, but he wished in his present paper to discuss some of the difficulties of its use. Of the action of radium our knowledge was poor, but there was one outstanding fact—namely, that quickly growing tissues, that is to say, cells which were in an active state of metabolism, were far more affected by radiation than more stable cells. All radiotherapy was based on this fact. It was not known why the quickly growing cells of a tumour should be sensitive to radium; but a direct action was evident in its effect on cells in tissue culture. Under radiation these cells showed a cessation of mitosis, but on removal of the radium mitosis returned. Further, an irradiated tumour, on transplantation, would not grow in its second host. Histological section of irradiated tumours showed that the cells in the vicinity of the radium were disintegrated. But this action did not explain why some tumour cells were more sensitive to radium than others. Tumours of the vulva, for instance, were much more resistant to radium than those of the cervix. On what did this depend? Was it the blood-supply or was it the histological structure of the growth? Hypertrophic carcinoma of the cervix was more radiosensitive than ulcerative carcinoma; possibly in hypertrophic carcinoma the cancer resistance of the patient was higher—a factor which must be taken into account. There was evidence of an indirect action of radium on the blood-supply in the obliteration of vessels by fibrous tissue; probably the fibrosis played its part in destroying the tumour, and at one time it was believed that the action of radium depended entirely on the formation of fibrous tissue. It was probable that the action on the tumour cells, the obliteration of arteries, and the stimulation of fibrosis all took part in producing the result, and that possibly the dying tumour cells gave rise to antibodies as well. It was still doubtful whether some wave-lengths had a specific action; some authorities believed the gamma rays to be selective in their action. Clinically, however, surgeons were tending to cut out the longer gamma rays by heavier screening. It was not yet decided to what extent a septic condition of the growth militated against radium treatment. Probably it had a markedly detrimental action on the results. Opinions still differed on the use of a large dose of radium inserted for a short time, and on the use of small split doses used intermittently for longer periods. At the present time small doses for long periods were more commonly used, but it was not known whether tissues exposed to repeated small doses acquired an immunity to further treatment.

Technique.

With such imperfect knowledge of the action of radium technique was bound to be empirical. But before results could be compared it was necessary to clear up the existing confusion about radium dosage. To give the number of milligramme-hours was not sufficient; 1·0 mg. might be inserted for 100 hours, or 100 mg. for 1 hour; both would give a dose of 100 mg.-hours, but the results would be very different. Any minutiæ on dosage must include the weight of radium element, the number of containers, the size of the containers and the thickness of their walls, the position of the containers in relation to the growth, and the length of time they remained in position. For carcinoma of the cervix there were three well-known techniques. First, the Stockholm technique, in which 120 mg. was applied to the surface of the growth on three occasions at intervals of one or two weeks, and remained in position for 24 hours. Secondly, the Paris technique, also a surface application, in which 60 mg. were used and left in situ for five or six days. And thirdly, the Brussels technique, in which 40 to 50 mg. were used and left in position for any period up to 15 days. At St. Bartholomew's Hospital a needle technique was used, in order to distribute the radium, and the containers were left in position for 144 hours. It was impossible to say which was the best of these methods, because there is no means of comparing identical cases. In nearly 100 per cent. of cases it was possible to clear up the primary growth, but the problem lay in treating the glands efficiently. Apart from dissection, this could be attempted in two ways: by X ray applications to the glands and pelvis, and by intra-abdominal radium. The technique which the speaker used for the insertion of intra-abdominal radium required a double operation. The abdomen was opened and 20 needles, each containing 2·0 mg. of radium element, were sewn round the pelvis; after a week the abdomen was re-opened and the needles were removed. When first using this technique he had packed the intestines away with gauze, but this had caused a severe reaction and he had discontinued it without any evil results. After five years over half of his cases treated in this way were still living. Radium used in conjunction with X rays was more effective than radium alone. It was not justifiable to treat carcinoma of the cervix by radium alone, inserted per vaginam, since the disappearance of the primary growth only could not be considered to be efficient treatment. Carcinoma of the vagina could be quickly removed by radium. Carcinoma of the vulva was considered to be markedly radio-resistant, but recent work with small doses spread over the vulval area and left in situ for 10 days to 6 weeks had produced good results locally. Treatment of the glands by embedding radium containers in Columbia wax spread over the whole inguinal area was probably the most effective method where sufficient radium could be obtained. Carcinoma of the body of the uterus was still best treated by hysterectomy; where this was contra-indicated, 50 mg. of radium left in the uterine cavity from 10 to 14 days, and combined with X ray therapy, had been of value. Chorion-epithelioma should also receive combined X ray and radium treatment where possible. In benign conditions an artificial menopause could be readily produced by insertion of 50 mg. of radium into the uterine cavity for 3 days; the cessation of menses might be temporary or permanent, but if it was temporary a second dose usually stopped further menstruation. Fibroids, if small and if the patient was over 40, could usually be treated successfully by radiotherapy. At the present time dogmatism about technique in benign conditions might be amusing but in malignant conditions it was wicked.

Position of the Radiologist.

Dr. J. E. A. LYNHAM, speaking for the Electrotherapeutic Section, said that the position of the radiologist was ill-defined; he was expected to consult with physicians, surgeons, and gynæcologists on any branch of their work, as well as to control all the electrotherapeutic apparatus under his charge. Coöperation between surgeons and radiologists was essential, and collective thought was particularly valuable in the treatment of malignant disease. In benign conditions an artificial menopause could be established readily with either X rays or radium, and it had been stated that X rays affected the ovaries while radium affected the endometrium. In carcinoma the effect of radium on the stroma was probably the more important action, while in sarcoma the results were obtained by the action on the cells. Early failures had been due to overdosage. In his experience the best results were obtained by the use of X rays following radium. Screening had become necessary because with unscreened radium the damage to neighbouring tissues had been so severe, and the present tendency was to increase the thickness of the screen. Where glands were involved a rapid enlargement took place if the primary growth alone was treated. An alternative method for the use of intra-abdominal radium to that of Mr. Donaldson was the attachment of the container to a retroperitoneal drainage-tube which could be drawn out later. This seemed preferable to a double abdominal operation, which recalled the aphorism: "One has to be very robust nowadays to be a good patient." Life could be prolonged in many cases by treatment of glands with heavily screened high voltage X rays or by the use of a radium searchlight, and the real test of such treatments was the length of life of the patient. Radiotherapy was not based on the principles of surgery, and applications should be continued for some time after the disappearance of the growth; recurrences could be slowed in their rate of growth, if not removed, by a fresh application of radium. He considered that a two-stage operation for treatment of a primary growth offered an effective technique; on the first occasion the needles were placed round the growth, and on the second occasion, after an interval of 14 days, they were inserted into it. It was important to remove all septic foci, such as infected teeth and tonsils, before irradiation, for they materially affected the results. In conclusion, he would say that the radiologists had never anticipated that radium might be used to replace operative treatment. A combination of the two methods was obviously much more valuable. Systematic and exhaustive trials of technique must be made. The subject was at its beginning, and personal views should always be submitted to groups of workers for assessment.

Treatment of Menorrhagia.

Mr. STANLEY DODD said that the production of an artificial menopause probably depended on the selective action of the gamma rays on the ovary. The return of menses in many cases showed that the rays had not penetrated to the deeper immature ova. Cases in which the production of an artificial menopause by radium was indicated were as follows: Where the menses were regular but profuse as in chronic subinvolution; with severe bleeding at the climacteric; in persons with pulmonary tuberculosis who were losing more than they could afford at their periods; in fat women with fibroids, or in women with fibroids and other contra-indications to anæsthesia; with severe dysmenorrhœa which would respond to no other treatment. The last was justifiable only if all other treatments had been tried unsuccessfully. As regarded other benign conditions, the use of radium in cervicitis was usually disappointing, owing to the infective condition present. To produce an artificial menopause the smallest dose of radium which would produce the desired effect should be used, and in an elderly patient the dose required was smaller than in a younger one. Complications of the treatment were pain, usually transient, which disappeared on removal of the radium; and malaise, which was best treated by rest in bed and a tonic. The results in his series had usually been good, with few recurrences of menses. A second dose had always stopped mentruation permanently. One cervix diagnosed histologically as precarcinomatous which he had treated with radium needles was now perfectly normal. Among his cases of carcinoma of the cervix he had a cure rate of 40 per cent. after five years. Radium eradicated the primary growth and then the glands were removed by abdominal operation, and intra-abdominal radium was applied. His technique was as follows: The cervix received three applications of radium; 14 days after the last the abdomen was opened and after removal of the regional glands two catheters were introduced, each containing five radium needles in series; the needles were 2·0 cm. long, contained 1·0 mg. of radium, and were screened by 1 mm. of platinum. One catheter passed from the sacro-iliac synchondrosis round the pelvis to Poupart's ligament, where it pierced the abdominal wall and was sutured. The other, bent in a crook, lay with its curved end in the obturator foramen, and its free end also piercing the abdominal wall. The peritoneum was sutured over both catheters which were withdrawn by gentle traction after seven days. Such a technique as this might solve the problem of intra-abdominal radium applications when the dosage had been more accurately determined.

Discussion.

Dr. RUSSELL REYNOLDS said that radiotherapy could not be dissociated from deep X ray therapy. In his experience it was important to use the split-dose technique. Large doses of radium lowered the resistance of both the tissues and the patient. With split-dosage a larger dose could ultimately be given. It was important to use X rays and radium in conjunction, since radium has a local action and X rays have a more general one. He had had good results from combined treatment, especially in tumours of the lung. In these cases the tumour still seemed to exist but the patient remained well for several years.

Dr. W. M. LEVITT said that X rays were a form of treatment complementary to radium since one was peripheral in action and the other central. After X ray treatment recurrence was usually local, while after radium it was generally deep. Both damaged the cancer cell, but the type of injury was probably different. In combined technique the sequence was of importance and he believed better results to be obtained if X rays were given *before* radium. He would be interested to know why Mr. Dodd preferred to obtain an artificial menopause by radium when it could be obtained safely and without discomfort by X rays.

Mr. Gilbert Scott said that the disappearance of the primary growth alone usually meant the disappearance of the patient after a varying number of years. Five years did not necessarily mean a cure; it was not the primary growth that killed the patient, nor the secondary involvement of glands; metastases in liver, spine, and thorax were the cause of death. We should not speak of cure until we could prevent the appearance of these metastases.

Mr. James Wyatt asked whether the speakers were convinced that in the production of artificial menopause the action of the radium was really on the ovary and not on the uterine walls. The menopausal symptoms in these cases were slight or absent. He had found radium to be of value in treating pruritis vulvæ, often when X ray applications had given no relief. Also in endometrioma radium relieved the pain and caused regression of the tumour.

Mr. Martin Oldershaw said that he believed the production of artificial menopause was due to the action of radium on the endometrium only. X rays gave symptoms much more like those of the artificial menopause caused by removal of the ovaries. He believed the recurrence of menses after radium to be due to an incomplete irradiation of the endometrium; the dose should be arranged to affect the whole lining. The advantage of radium was that a thorough examination, with curetting, could be made under an anæsthetic before its introduction.

Mr. Duncan Fitzwilliams said that the physicists say that the gamma rays would not penetrate from the uterus to the ovary, but he had seen a case of cerebral tumour treated with radium where the hair on the side of the head near the radium turned white and fell out. The hair on the opposite side of the head, five and a half inches away from the radium, did the same thing. In removal of glands block dissection was still the sheet anchor; he doubted the value of retroperitoneal radium. But it was wrong to confine oneself to one method of treatment, and he believed combined treatment to be of value, though he had been repeatedly disappointed in the results of X ray therapy for carcinoma.

Mr. Patterson gave some figures, which he said were incomplete, collected during the past two or three years at St. Bartholomew's Hospital. Although not sufficient for exact analysis these tended to show that the more immature the type of cell composing the tumour, the better is the prognosis for radium treatment.

Mr. R. E. T. Strachan mentioned some practical difficulties in the insertion of radium into a friable carcinomatous cervix. He considered that radium treatment was prolonging life, but that cure was not yet in sight. In a certain proportion of cases of carcinoma of the cervix treated with radium, fistula occurred. He was not clear whether it was due to the radium or whether it would have occurred in any case.

Dame Louise McIlroy said that radiologists should be present at operations and advise on the insertion of radium. She had found a small but prolonged dose of radium valuable in the menorrhagia of puberty; she had used radium as a preliminary to operation, also in cases where bleeding fibroids had caused collapse. She would be interested to know whether, in cases with severe anæmia, radium did not tend to aggravate the anæmic symptoms. In some cases of menorrhagia with septic teeth and tonsils the removal of these foci caused a cessation of symptoms without the need of radium.

The Chairman said that radiotherapy should be regarded as supplementary to surgery. Radium should be used to produce an artificial menopause when arrest of bleeding was the primary consideration, and X rays when the menopause was desired primarily.

Replies.

Mr. Donaldson said that radium should be used to produce artificial menopause in cases of irregular bleeding, after a thorough examination of cervix and uterus. Pain was usually due to proctitis and passed off on removal of the radium unless some more serious cause was present. Anæmia should be corrected by blood transfusion before the use of radium. As to artificial menopause, the ovary was very radiosensitive, and might well be affected by radium in the uterus.

Dr. Lynham said that while radium in the uterus might have some effect on the ovaries this was probably small; the uterus was more likely to be affected. He had had good results from radium in endometritis using small doses for a short time with thin filters. Pain was usually transient but occasionally severe.

Mr. Dodd said that no one knew whether the ovaries or the uterus were affected in bringing about the artificial menopause. Probably both underwent some change.

SECTION OF SURGERY: SUBSECTION OF PROCTOLOGY.

At a meeting of this Subsection on Feb. 12th, with Mr. Cecil Rowntree, the President, in the chair, a discussion took place on

Factors Making for Safety in the Surgery of Colon and Rectum.

Mr. G. Gordon-Taylor said he had no new precept to inculcate nor any very novel point in technique to submit which was likely to bring about a marked diminution in mortality; he would deal mainly with the factors making for safety in the surgery of cancer of the large bowel. In this branch of surgery safety of operation was not the only consideration, for the most thorough extirpation of the disease held out the brightest prospect of cure. In cancer surgery the watchword should be "efficiency with safety."

The mortality from radical surgery in cancer of the colon was capable of reduction, as a study of statistics would show. Mr. Grey Turner had rightly insisted that in surgery operability and mortality went hand in hand, and had stated that he regarded a 5 per cent. mortality for colon resection for cancer as representing the acme of judgment and the perfection of technical skill. In the removal of a carcinomatous colon, success or failure depended upon the manipulation necessary to deliver and resect the tumour and upon the healing of the anastomosis required to restore the continuity of the intestinal canal. It was certain that preliminary drainage had a profound effect on the septicity of the bowel contents, and even on the bowel wall itself at the site of the new growth. When a cancerous cæcum had to be removed the speaker was not sure that a most valuable measure of safety was not a previous ileo-transversostomy. If a cæcostomy was to be performed as a preliminary procedure, it was not enough to make a valvular cæcostomy; an actual artificial anus should be established, so that the fæcal stream was largely or wholly deflected. But valvular cæcostomy could advantageously be used as a temporary measure in cases where resection of the large intestine was necessary because it was secondarily involved in some morbid process which originated in an adjacent structure. With the increase in his experience, Mr. Gordon-Taylor found himself preferring more and more the two-stage, or perhaps the three-stage operation; he was sure the mortality was lowered thereby. Preliminary blood transfusion was especially indicated in cases in which there had been intestinal hæmorrhage, whether occult or otherwise, and it was the most valuable method available for treating post-operative shock. Of preliminary immunisation he had had but a small experience. Bowel mobilisation was of course very important. He had no particular views on how anastomosis should be carried out. When an attempt was made to perform a really radical extirpation of the potentially affected zone he employed end-to-end suture or a side-to-side junction; he did not like so much the end-to-side method of union. What was important was the manner of performing the anastomosis. The exteriorisation methods of the Paul-Mikulicz type of colonic resection gave the lowest mortality. As regards methods of intra-abdominal anastomosis, it should be borne in mind that many of these patients were elderly, and many had degenerative changes in their vessels, so that a tendency to thrombosis in arterioles and veins supplying the bowel wall was aggravated by bowel sepsis and the manipulations necessary in the operation. He avoided all large crushing clamps, contenting himself with a small Payr clamp at each end. Where possible, he avoided the middle line for his incision and the mid-stream of the abdominal cavity, making his attack, where possible, at the sides or in the flanks close to the tumour; and he always drained. In the event of a leak a drain was a great help.

Mr. Gordon-Taylor proceeded to deal in detail with the questions involved in extirpation of a cancerous rectum, remarking that the surgery of malignant disease was the surgery of the lymphatic system. The only really radical operation for a carcinomatous rectum was that of Ernest Miles; but the speaker had fairly often been compelled by circumstances to practise what he knew to be an imperfect operation. It was difficult to see how the figures of Mr. J. P. Lockhart-Mummery—from 2 per cent. to 3 per cent.—could be beaten. In performing the abdomino-perineal excision Mr. Gordon-Taylor had found that taking it as a two-stage operation made it much less formidable. In the case of a malignant rectum he always did a preliminary left iliac colostomy, doing the extirpation of sigmoid and rectum at a later date. At present there was a tendency to utilise radium therapy in addition to extirpation of the rectum by the perineal route, but the speaker regarded this as no more than a hypnotic piece of technique on the part of the surgeon. In recto-sigmoidal growths it was agreed that the abdomino-perineal method was the one needed. It was a severe one, and Lockhart-Mummery admitted a mortality of 27 per cent. from it. The greatest factor for safety in the management of a carcinomatous rectum was the judgment of the surgeon; and he would be the most safe and successful who employed the appropriate operation for the individual case.

The Significance of Obstruction.

Mr. Ivor Back expressed the opinion that any member of the Section could remove a portion of a normal colon and do an end-to-end anastomosis with absolute safety to the patient if he cut the colon obliquely, taking care of the vessels, and being careful about asepsis. Further, no member could do a primary resection of the colon with end-to-end anastomosis in the presence of obstruction without preliminary drainage and avoid killing the patient. Between complete obstruction and an entire absence of it there was every gradation, and there must be a stage at which obstruction had not yet reached the danger point, and where localised resection of the colon could be carried out without primary drainage. When the sigmoidoscope revealed a small carcinomatous ulcer of the colon which had not extended round the bowel and there was no obstruction, it was feasible and safe to do resection and end-to-end anastomosis. He asked what clinical, radiological, or other means were available for determining whether the degree of obstruction was such that a primary resection could be done without danger, or whether it was necessary to proceed to some of the other means of preliminary drainage. The moment macroscopic obstruction was present the problem became a difficult one. The safest operation which he knew for resection of a portion of the colon was that named after Paul, but it had grave disadvantages. At the second stage the colon which had been exposed was thick and œdematous, and suture of the œdematous colon was difficult. Further, however well the suturing was done and the operated part was put back beneath the rectus, in his experience there was invariably leakage, and this was tardy in healing. He thought it would be a good plan to make it a one-stage operation; to bring out the loop, fix it to the parietal peritoneum all round it, and to the mesentery, resect, and put the anastomosis back between the parietal peritoneum and the rectus. He had not tried it, and it was possible it might leak, but he did not think there was a real risk of peritonitis. He did not favour the side-to-side anastomosis, which had many disadvantages. He practised end-to-end anastomosis, either with suture or by Pringle's method. In the latter, however, the clamps did not take up the mucous membrane on both sides, and there was a risk of hæmorrhage at the point of junction. Still, Pringle's was a very good operation. As to the treatment of rectal carcinoma, he favoured the method of Ernest Miles. Admittedly it carried a high mortality; in his own cases it had been about 20 per cent.

Mr. Lionel Norbury said it was very difficult to render the large bowel aseptic, but a near approach to this was secured by frequent washing before operation in cases of chronic obstruction. He hoped soon to be using the new subaqueous apparatus for bowel irrigation, which promised well for this purpose. In the surgery of the colon the anæsthetic was very important. Spinal anæsthesia diminished shock, but in some cases it was rather dangerous—*e.g.*, in the presence of bronchitis—and practical inversion of the patient was needed. He was disappointed to hear lateral anastomosis was not recommended, as he leaned towards it, especially in resection of the sigmoid. He could not understand any surgeon not draining after the operations under discussion, as it certainly made for the safety of the patient. He had been very pleased to hear the opener's reference to temporary cæcostomy. Perineal excision of the rectum he did as a two-stage operation: first cæcostomy, and excision 7 to 14 days later.

Mr. W. B. Gabriel did not think that after valvular cæcostomy there was likely to be any deflection of the fæcal current; the operation succeeded if a suitable tube was put in.

Prof. A. W. Sheen agreed with the performance of lateral anastomosis following resection of the growth. With regard to the use of radium in connexion with malignant growth of the rectum, the difficulty was that the present attitude viewed radium as something to be used if there was a reason against operation. The question was whether there was likely to be much success with radium if that attitude were persisted in. He spoke of a case of very early carcinoma of the rectum, but which could easily be felt. It was localised on the lower rectal posterior wall. It all disappeared after two applications of radon seeds. Whatever was done, he thought operation for carcinoma of the rectum would always be a dangerous one.

Prof. Arthur H. Burgess thought that full credit should be given to Paul for the operation with which his name was connected. He, the speaker, had used spinal anæsthesia extensively, and, given control, he was sure its employment considerably diminished the operative risks.

Mr. E. T. C. Milligan gave details of some cases which had come to his notice and which, on account of wrong treatment, must be classed as tragedies. He had been in the habit of doing cæcostomy for obstructed growth of the splenic flexure, also of the pelvic colon.

Mr. Turner Warwick said it was difficult to know why operation done in two stages should show a lower mortality than when done at one attempt, but it certainly was so. He considered that the abdomino-perineal operation was well within the capacity of the average surgeon, and it did not call for any expert nursing experience. He contended that new growths of the colon were exceptionally malignant.

Mr. Gordon-Taylor, in reply, said that the tragedies in connexion with minor operations which Mr. Milligan mentioned constituted a strong argument in favour of preliminary cæcostomy or preliminary drainage of the bowel. He objected to the Coffey operation.

Acetylcholine in Relation to Abdominal Surgery.

Mr. A. Lawrence Abel sent a communication on this subject, which was read by Mr. G. Parker. Hunt and Taveau, he said, testing acetylcholine in 1906, found that it lowered arterial pressure. Choline seemed to be a breakdown product which was formed during the normal metabolism of the central nervous system. Excreted into the wall of the alimentary canal, it exerted a hormonic action on Auerbach's plexus. Work in Magnus's laboratory in Utrecht showed that paralysis of the bowel produced by chloroform poisoning was quickly relieved by intravenous injections of choline hydrochloride. Acetylcholine produced in human beings a lowering of arterial blood pressure; it had an anticoagulant action on the blood in vitro, and also an anti-anaphylactic power. It was chiefly indicated in Raynaud's disease, gangrene arising from arteritis, intermittent claudication, arterial hypertension and angina pectoris, retinal artery spasm and thrombosis, encephalitis, profuse sweats in tuberculosis, and alimentary disturbances. It was of value, too, he said, in cases of acute and chronic constipation. For a very severe abdominal case, when, on being seen for the first time, the patient was in extremis, he gave 0·6 g. of acetylcholine intramuscularly; for a less severe case, 0·2 g. at one, two, or three-hourly intervals.

CHELSEA CLINICAL SOCIETY.

DEFÆCATION.

A meeting of this Society was held at the Rembrandt Hotel, Kensington, on Feb. 18th, under the presidency of Dr. Hayward, when a discussion on Defæcation took place.

Dr. Harold Pritchard opened the discussion. He said that this age-long function was first intelligently written about in 1833 by James O'Beirne, and those writings were the foundation of subsequent thought. Seventy years later, Cannon, in America, published some interesting X ray observations on defæcation in the cat. In recent times more light had been thrown on the process by Dr. A. F. Hurst than by any other authority and he was responsible for most of the modern conceptions of it. As soon as a meal was taken, there was set up a series of peristaltic nervous contractions and impulses in the whole intestinal tract. After a meal the small intestine was always full, as well as the stomach. But this was not true of the large intestine. Here there occurred at considerable intervals a mass peristalsis; the contents of cæcum and ascending colon were transferred with one movement to a site further along the canal. The descending colon filled up from below, and when the pressure on the contents reached a certain intensity, those contents were projected into the rectum, and at this stage there was instituted a call to defæcate. The normal animal emptied the bowel as soon as this stage was reached. In the human subject that was not permitted; the whole trend of what was called civilisation was towards preventing that impulse having full play, thus paving the way to habitual constipation. The impulse coming several times a day, it was essential, in the speaker's view, that the rectum emptied at least twice in the course of the 24 hours; this habit was seldom observed, though the ordinary man would see that he did defæcate once a day. The average woman would be content with anything between once a day and once a week, so that one found constipation or other error of the defæcatory process was quite common in the female sex If the levator ani were trained to oppose the natural desire for evacuation, there would result an accumulation of ever-hardening fæces, and then not only was it difficult, but also painful to get rid of this accretion. Ordinarily the contents became less fluid as the rectum was approached, and the longer they were retained in the latter, the harder they became. This was the condition known as dyschesia. The only treatment of this which was rational was to empty the rectum by means of an enema, not by aperients.

The effects of constipation were very far-reaching and it was not his intention to enter into them. Diet, however, was very important, especially the amount of fluid taken. He supposed that most people drank too little fluid. Water, taken first thing in the morning, before dinner, and again the last thing before retiring, was one of the most valuable adjuncts to the procuring of a regular action of the bowels. As to drugs, he reminded the meeting that it had been declared by a Chancellor of the Exchequer that £400,000 per annum was recouped by the Exchequer for Stamp Duties on proprietary medicines, 90 per cent. of this being probably for the correction of constipation. It represented about three million pounds spent every year on these medicines. When the bowel was loaded with hard, solid fæces, it was absurd to flog the patient with aperients. A very good rule in such cases was to oil from above, and wash out from below.

One could not neglect, said Dr. Pritchard, consideration of the psychological aspect of this question of defæcation. It was well known that a mental upset, or some agitation of the central nervous system, would largely influence the intake of food, and its digestion. He was not a great believer in psychology as applied to medicine, but of this influence of the mind on the food he entertained no doubt. Psychology taught that the child derived a good deal of satisfaction, even pleasure, from the act of defæcation; that, however, was a matter of opinion. It seemed equally certain that the child had a tendency to become constipated, and so it sowed early the seeds of an aberrant defæcatory process. Children gave the defæcatory processes and demands free play, largely disregarding the sociological and æsthetic aspects; but as education and social amenities increased, the tendency was more and more to hold the function in check, so that while the first part of life was spent in learning how to defæcate, the latter part was spent in learning how to overcome constipation.

Individual Variations.

Mr. Ivor Back agreed that in savage races and in animals in the wild state, defæcation was truly a post-prandial function—i.e., the bowels were emptied after each meal. But in civilised communities that would be grossly inconvenient, and so house-trained man had accustomed himself to making a defæcation once in 24 hours suffice. That, however, was not the only ritual which was consistent with perfect health; he was sure all those present had patients who were accustomed to go three and four days or longer between actions of the rectum. In such cases one was likely to do more harm than good by insisting on a system of mild or severe purgation, as it meant upsetting the person's natural rhythm, in addition to the risk of making the patient a drug addict. A Dutch surgeon, Treowen, reported a case in which the bowels were opened once every three months; another said a patient went five months between these acts, while De Villiers had a patient who went once in two years. Also there was the famous case of Emily Plumby, born in 1850 with an imperforate anus, who lived 122 days without any evacuation whatever, and during that time she had only occasional nausea and regurgitation of her mother's milk. They were classical cases; but while he was a student there came to hospital (St. George's), with nothing important the matter with her, a woman who when asked if her bowels were regular said they were. The house surgeon followed up the question with "So you have an action of the bowels every day?" To that she replied in the negative, adding that all her life she had had four actions of the bowels every year. She was given treatment for the complaint she came about, and he believed she was still having an action of the bowels quarterly. She confessed, however, that it was "a bit of a business," and when it was over she was accustomed to go to bed for 36 hours. Perhaps the total time spent over the function did not greatly exceed that spent in smaller amounts by ordinary folk. Fleck reported a case who had only six actions of the bowels a year, and told the patient that it was dreadful. He sent the man to take the waters at Marienbad, where he drank freely of them, and within five weeks of going there he died. This showed that harm could come from interfering with the natural rhythm of the particular body. For that reason he was opposed to the use of purges and various forms of paraffin in people who did not seem to be suffering from their long periods between motions. Sir Frederick Treves had published a case of a woman who was in the habit of taking large doses of magnesium sulphate for constipation. She passed some of it each day, but some remained behind; she died, and then a ball of magnesium sulphate was found blocking the ileo-cæcal valve.

Aberrations in the constitution of the dejecta were more important than aberrations in the periodicity of the act. Many people accustomed to a city life said their motions were broken up, and the speaker regarded this as an indication of a low degree of colonic streptococcal infection, perhaps not enough to be dignified by the term colitis. Its frequency could not be wondered at by those who had watched the events attendant on the baker's daily delivery of bread. A loaf would be dropped in the gutter, and retrieved and delivered at a house without any attempt at cleansing. In more extreme degrees the motions were tape-like. This kind of motion was more often the result of a squeezing of the fæces by an inflamed colon in a state of spasm than of a definite organic obstruction. In very many cases the cause was an obstruction at the anal orifice, sometimes as a result of a badly performed operation for piles. In the more extreme degrees of inflammation, colitis proper, there was a further breaking up of the fæces—namely, diarrhœa.

He regarded persistent diarrhœa as a more serious symptom than continued constipation, unless the constipation marked a departure from that person's normal rhythm—i.e., after going along well after a mild purge he found he needed definitely to increase the amount. He regarded this latter as one of the earliest indications of carcinoma in some part of the large intestine. Any case of persistent diarrhœa called for the use of the sigmoidoscope, and a microscopical examination of the fæces should be made on three or four occasions, one negative result being disregarded. Blood in the motions was, most often, an evidence of some morbid condition of the anal canal, especially if its presence be constant; and the commonest causes were piles and fissure. If there was no anal cause, blood streaking the motions should be regarded as of serious import, as being the first sign of carcinoma. He described a case of the kind which was diagnosed very early in this way, the carcinoma having a stalk. Five years after removal the patient remained quite well. Lastly, he referred to the class of case in which a middle-aged woman passed constipated motions, with mucus. He had never been able to discover a focal cause for this condition, and he leaned to the view that it was an accompaniment of an unhappy private life,

Constipation in Women.

Dr. F. J. **McCann** did not think women as a whole were quite so constipated as was generally supposed. He fully agreed that what was so important in this matter was the bodily rhythm, and that not every person needed to, or had a call to, evacuate after each meal. One case of great reluctance to go to stool he traced to the presence of a tear in the perineum. Repair of this led to a very satisfactory regularity of toilet. And it should be remembered that one result of frequent child-bearing was an eventual wide separation of the levatores ani muscles, which greatly lessened her power of expelling motions. Sometimes the results of a Whitehead operation for piles were disastrous. Mucous polypi he looked upon as danger-signals, and he noted Mr. Sampson Handley had recently lectured on the relationship of polypi to carcinomata. Cathcart, of Edinburgh, had done much in pointing out the essential similarity between innocent and malignant disease. The riddle of the simple tumour was a very deep one; we did not yet know what were the laws of growth, nor why a tumour, long resident in the body without increasing in size, should suddenly take on rapid growth.

Dr. H. B. **Carlill** said that he had seen obstinate constipation in subjects of tabes dorsalis, so bad that a general anæsthetic had to be given so that the lower bowel could be cleared out. He agreed that it was a sudden alteration in the habits and rhythm of life which was the important consideration in the subject under discussion. Nurses often gave enemata when there was nothing within the reach of the finger to remove.

Dr. **Murray Levick** remarked on the paucity of the references to diet, which he regarded as very important in this connexion. There was a close analogy, he considered, between constipation and gout. Two generations ago most people of position suffered from gout, and much brilliant work was done on it. The chief reason for its greatly diminished frequency nowadays was that as a rule people did not now eat too much. When the general population had given up using white flour for bread and pastry, and had taken to eating whole grain, with the husk and the germ, constipation would, he thought, disappear. Several of his patients had given up white flour, with very great benefit, and he did not know of anyone who had taken to whole meal flour and who continued to be constipated.

Mr. L. C. **Rivett** said that, speaking as a gynæcologist, he had many times watched the newly-born infant defæcate after each meal, and had come to the conclusion that the stimulus of taking a meal was normally responsible for the opening of the bowels. Defæcation could be inhibited by mental effort, and he was sure that much could be done by instituting a very hard-and-fast time rule of visiting the rear. He agreed that a large proportion of the women of the country were constipated, and one reason of this was that they did not take sufficient fluid; certainly they took less than did men.

Dr. A. **Orliansky** said that people varied greatly in the matter of emptying the rectum. In some the meal progressed slowly along the intestinal canal and constipation was caused by combination of spasm and atony in different parts of the bowel. Another type was that in which there was cæcal stasis. In these cases it was found there was still a trace of the barium meal in the cæcum 48 hours to four days after it was taken. The food caused abnormal fermentation, and a pool of infection was set up, and as a result of irritation of the bowel, loose stools, even diarrhœa, resulted. A further type was dyschesia.

Diphtheria Immunisation in Manchester.—In regard to the scheme for immunisation against diphtheria introduced in October, 1928, the report to the Manchester Public Health Committee of Dr. Veitch Clark, M.O.H., shows that, in all, 3745 people had been treated up to last December. Four people contracted diphtheria before they had received the requisite number of injections, but there was no instance of a fully immunised person suffering from the disease. No serious reactions or ill-effects had occurred among any of the patients, nor was there any appreciable effect upon attendance at school of the children who were treated. The treatment had been provided free at certain institutions, and in all schools, and in addition the necessary material was supplied freely to 19 general practitioners for private use.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

A MEETING of this Association was held on Jan. 28th at the British Medical Association House. In the absence of Miss FRANCES HUXLEY, the President, the chair was taken by Miss ELIZABETH BOLTON. A discussion on the

WORK OF MEDICAL WOMEN IN INDIA

was opened by Lady BARRETT. She outlined the development of the work since the time when Dr. Swain, of New York, joined two missionaries who had begun to train orphan girls in physiology and hygiene. Dr. Swain added to their training some knowledge of medicine, nursing, and compounding, and probably her pupils were the first Indian women to be trained in nursing and dispensing. British medical women followed later, and the sufferings of purdah women led Queen Victoria to command Lady Dufferin to do all she could to relieve the situation. Lady Dufferin collected money from Indian princes, and thus formed the Association which long bore her name, and which in 1913 became the Women's Medical Service of India. The proposal to constitute an official Women's Medical Service, corresponding to the I.M.S., was at this date finally rejected, but the Government sanctioned a subsidy to enable a Women's Medical Service to be carried on by the Countess of Dufferin Fund. With this meagre concession the Service had struggled to carry on, but the position to-day was that the funds barely justified the support of the 42 medical women in the Services and of the hospitals which rely on the Fund for upkeep. The difficulty in obtaining an adequate subsidy from the Government arose from the present constitution of the Service, since medical aid is one of the departments relegated to the provincial governments. The Government of India refused to concern itself with the support of the Fund, and unfortunately the Provincial Ministers tended to pursue a policy of economy which did not allow of efficient grants for medical services. Money was spent on the promotion of the indigenous system of medicine, and hospitals were built without ensuring that sufficient funds were available for fully qualified medical women to be put in charge of them. Moreover, even in the areas which are under the direct administration of the Government of India, the Indian women, and especially the purdah women, were most inadequately served. The Association of Medical Women in India endeavoured to make these areas a special charge, but it could do very little when it was faced at the same time with the need of supplying and preparing medical women for professional appointments and with the charge of hospitals for women in the various provinces. It was now urgent that the Medical Women's Services in India should be put on a proper basis. The unwillingness of provincial governments to appreciate in any way the desirability of making grants for medical work for women was illustrated in the Cama hospital in Bombay, where many reforms were necessary, and in the Agra Hospital for Women. In connexion with the latter hospital Dr. Margaret Balfour had contributed a letter to an Indian paper, in which she pointed out that the Government had recently installed electric light in the mental hospital, but had persistently refused to do so in the Women's Medical School and Hospital. One night recently a uterus was removed, two Cæsarean sections were performed, an appendix was removed, and five mothers were delivered naturally, all by lamplight. That the Government would provide light for criminal lunatics while withholding it from these unfortunate mothers indicated, in Dr. Balfour's view, that the omission was not due to lack of money but to the slackness of the authorities when the matter of the benefit of women only was concerned. She pleaded that hospitals run by men and women should be placed on an equal footing as regards staff, equipment, and appliances, the only criterion being the importance of the work done in each place. Efforts for the improvement of medical work and education were going on in various parts of India, but the danger was that even fine buildings might be coupled with efficient equipment and personnel, still more probably with inefficient nursing.

Lady Barrett proceeded to consider how this enormous problem should be tackled. Most medical women who had worked in India were agreed on the importance of the appointment of a fully trained medical woman in each province to hold a position at least as high as that of assistant director. Such a woman should be in a position to organise work for maternity and child welfare, and later to connect it up with hospital work. Many people who had studied the question considered that a useful first step would be the appointment of such a medical woman, and also one in charge of a central fund from which grants might be made to the provinces. Ultimately there might be established a revised Indian Medical Service for men and women with equal pay and privileges. This scheme was favoured by many of the younger medical women working in India, but it might take years to come. Another idea was that, side by side with the I.M.S., an official women's medical service should be recognised, with members adequately paid. The first step suggested by Lady Barrett would be a suitable beginning to either of these schemes. The difficulty would be the finding of the money. In her view, the principle of a grant, equal to the amount raised by the local authorities, would be successful in India as it has been in England. Provincial governments might be willing to spend 50 per cent. on work done by voluntary agencies or recommended to them by a woman medical officer of standing if a central source of supply provided the other 50 per cent. Indian women were taking part with enthusiasm in child welfare work. Lady Barrett believed they would support with equal enthusiasm proposals for a unified women's health service for India.

Discussion.

Dr. ANNETTE BENSON quoted statistics showing the inadequacy of the provision of medical women, nurses, and hospitals for women patients in India. It was almost impossible for those who had never been in India to realise the vast expanse of country inhabited by illiterate people, all as ignorant of hygiene as the goats and rats who lived with them. A favourable sign was the real interest which had recently been aroused in child welfare work and health exhibitions. Individual enterprise could not fill the need; medical women must be organised in the Government service, for their own protection, and to keep their work up to standard.

Dr. TURNER WATTS said that the Indian women who had entered the medical profession were, for the most part, engaged in private practice, where their quiet unostentatious work had had an influence on many homes, and must not be forgotten in any estimate of what had been accomplished. These Indian women, as well as those working in medical missions, and, indeed, nearly all those who had worked in India, had found clinical work so exacting that little time or strength was left for anything else. A few had achieved great success in teaching, notably in the Lady Hardinge School and Hospital, but in certain directions further development was required, especially in pathology and research, and in preventive medicine.

Dr. NAWAL KISHORE spoke of the conditions in country districts and small towns. The majority of maternity cases were conducted by the indigenous dais, who were illiterate and ignorant women. The profession of Traditional Dai was handed from mother to daughter or from mother-in-law to daughter-in-law. These women had no idea of asepsis, and their methods of conducting labour were very crude. Attempts were made to improve the indigenous dais by training, but the majority who attended classes were over 50 years of age, too old to understand or grasp anything new. They were intolerant of aseptic methods, and it could well be understood that one year's training did not lead them far towards acquiring the desired standard of work. After this training they were given a certificate written in a language which they did not understand testifying to their efficiency in midwifery. With this certificate they were well fortified to defend themselves. Dr. Nawal Kishore held that it was imperative to establish an efficient service for the teaching and training of midwives who should all be of a higher standard than those who had hitherto presented themselves. At the very least they should have a reading and writing knowledge of their own vernacular. She begged that medical women who desired to render service to the suffering women of India should use their influence to raise the standard of efficiency in the training of midwives in that country.

Dr. V. PILLEY gave some account of the Lady Hardinge Medical College and the organisation for training medical students.

Dr. B. NATARAJAN commented on the good feeling between men and women medical students in India, and stressed the importance of employing Indian medical women for work among Indian women. Sometimes European medical women attempted to work among the people without having studied their language, and naturally they could not gain the confidence of their patients.

Mrs. RAMA RAO spoke from the point of view of a social worker. She appealed for the formation of some scheme which could be considered and supported by the All-India Women's Conference. The great thing was the teaching of sanitary conditions in villages and the training of more dais for maternity work in outlying districts. These dais worked for a wage of a pound per month, and the immediate provision of many trained dais would be of greater benefit to the women of India than the slow organisation of a highly efficient service. In her view it was important to keep the indigenous dais, even if they had to have a two years' training instead of one. This hereditary profession was a factor of life in India which could not be ignored, and no efforts must be spared to make it efficient.

Reply.

Lady BARRETT pointed out that the proper training of midwives depended on an efficient maternity hospital, staffed by expert medical women, where midwives could see labours conducted under good conditions. It also implied a service of medical women who could show them how to adapt their training by midwifery work in the patient's own home. It was for this reason that she considered that the best method of advance was by the appointment of medical women to the provincial governments as directors of maternity and child welfare.

LIVERPOOL MEDICAL INSTITUTION.

AT a meeting of this Institution on Feb. 13th Mr. C. THURSTAN HOLLAND and Dr. J. M. W. MORISON (Edinburgh) opened a discussion on

Radium in the Treatment of Malignant Disease.

Mr. HOLLAND began by saying that radium never had been and never would be the cure for cancer. Radium, like the knife and diathermy, was essentially a local remedy and no merely local attack could ever be entirely successful. Methods of raising money had unfortunately led the public to believe that, given enough radium, cancer need no longer be feared. The published statistics were unreliable in estimating the real results. The term "cure" should not be applied to the so-called five years' cure; in the large majority of cases the mere removal of a tumour was not enough, a general infection had already taken place, and it was merely a matter of time before some kind of protection gave way and recurrence or metastases followed. Considerably over half the yearly deaths from cancer were from disease of the gastro-intestinal tract and its appendages, and this could not be a very hopeful field for radium treatment.

Dr. MORISON said that the National Radium Commission did not regard the question of the use of radium in the treatment of cancer as one that was settled, but rather that the subject was one which called for careful inquiry. The trend of radium therapy in the great continental centres, he thought, was the avoidance, whenever possible, of the direct introduction into the tissues of tubes and needles, the line of advance being the development of the surface applicator, designed in such a way that the distribution of tubes and needles on the outer surface gave what was for all practical purposes uniform irradiation of the skin surface. He regarded the work of Murdoch and Stahel at l'Hôpital Burgmann in Brussels as a genuine advance. Radium therapy was still in the experimental stage, but the results obtained justified its use and justified further research, both clinical and experimental.

Mr. G. C. E. SIMPSON thought the openers had taken far too pessimistic a view, that the experience of surgeons in the diagnosis of cancer and of the results which might be obtained in individual cases was such that it should not be eliminated by introducing a new class of specialist, the radiological expert on cancer. While agreeing that in every centre the surgeon should be able to seek the advice of such experts, he considered the surgeon was justified in using radium if he had made himself familiar with the results obtained and the treatment used in the great surgical clinics which had advanced radium treatment in recent years. Such treatment in operable cases had the advantage of saving mutilating operations, and there were many places, such as the floor of the mouth, where radical surgery of cancer was not only highly dangerous but almost hopeless and where radium treatment gave at least great ease and in many cases apparent cure. After all, whatever the dangers of inexperienced treatment, cancer itself was a fatal disease.

Mr. F. STRONG HEANEY held that Mr. Holland had proved his thesis that radium was not "the cure" for cancer, but surgeons and gynæcologists had really not an exaggerated or false idea of the value of the remedy. Under the present voluntary hospital régime appeals for funds must be made by laymen, and were, in fact, made without reference to medical men. The profession itself was fully aware of the limitations of this very valuable weapon in treating cancer. Objection had been taken to the five years' standard of non-recurrence, but the only way to compare results was to adopt some standard of comparison, be it five years or otherwise. Cases must be selected by someone in a position to judge the possibilities of surgery. The collaboration of the radiologist and the physicist was, of course, indispensable. Whether in the hands of surgeons or radiologists methods were still largely empirical. As between radium and deep therapy radium would be preferred until more and better results from deep therapy were recorded.

Dr. RAWDON SMITH, whilst agreeing that certain of the methods for raising money were much to be deprecated, hoped that nothing Mr. Holland had said would prevent the public subscribing for radium in Liverpool, where both research and radiotherapy were behindhand.

Mr. PHILIP HAWE said the estimation of the dosage of radium in terms of ergs, although ideal, seemed to prevent many difficulties. In the case of superficial tumours it was a time-consuming calculation, but with deep tumours whose size could not be accurately determined it did not appear of much value to him. The bomb treatment was justifiable only in the most expert hands and as even then it was both dangerous and of doubtful value it was unlikely that it would ever come into more general use. Mr. Hawe had been much impressed during a visit to Brussels by the importance of having at one's disposal for the treatment of malignant disease all three methods—radium, surgery, and X rays—if the best results were to be obtained. For instance, carcinoma of the rectum was probably best dealt with by a preliminary colostomy, then radium after eight days and in two months' time a perineal resection (Newman and Coryn). The results were better than those of surgery alone and far better than could be hoped for with radium alone. Operable breast cases were dealt with by a preliminary course of X ray therapy, then operation on the usual lines, and finally another course of X rays. In inoperable cases and superficial recurrences radium was used, and for the deep recurrences X rays were used. With extensive irradiation regular blood examination was of great importance; leucopenia was a danger signal.

Prof. W. J. **Dilling** said that from personal knowledge of beneficial results at the Radium Institute in Paris he was convinced that further supplies of radium were necessary in Liverpool in order that patients might not be denied the relief and benefit which this therapeutic agent could afford in certain types of malignant disease. In Liverpool, with its complexity of hospitals, he felt that the ideal system for the effective utilisation of radium was the establishment, under the supervision of the University, of a radium institute where a directing medical officer, specially trained in the physics and modern technique of both X ray and radium therapy, could guide surgeons as to the dosage and methods most promising of success and could organise research with a view of improving technique and results. The present policy of the Radium Commission to lend radium to only one hospital in an area was not, in his opinion, designed to facilitate the use of this therapeutic agent for the most deserving and appropriate cases.

Dr. C. O. **Stallybrass** inquired what was the best way of securing the coöperation of the surgeon and the radiologist and whether the Radium Commission were taking any steps to place the training of radiologists in the treatment of cancer on a sound basis.

Mr. **Frank Jeans** said he did not consider Mr. Holland and Dr. Morison pessimists. They were simply telling the truth—that the treatment by radium or by surgery was productive of equally good or bad results. Radium had not yet supplanted surgery. Naturally patients preferred radium, but the position was that there was a great deal of cancer and very little radium and surgeons were forced to operate nearly as much as ever. The extravagant claims for radium were perhaps (but he did not admit this) partly pardonable because it was known that the public would not subscribe for research, but would for a promise of cure.

Mr. **Holland** and Dr. **Morison** replied.

Protrusion of the Mandible.

Mr. G. C. E. **Simpson** and Mr. H. G. **Watkin** described a case of protrusion of the mandible in a man of 28. His lower teeth were 19 mm. anterior to the upper and he was unable to eat well and ashamed to eat in public. The condition, they said, is in some cases congenital and in others caused by finger sucking or early loss of temporary incisors—leading to the lower teeth getting too far forward. Once started it tends to increase from mechanical causes unless checked and dental measures are most valuable before the loss of the deciduous molars. Angle and Whipple have devised an operation of division of the mandible on both sides at about the level of the premolar teeth, but there are objections to it—namely, first the injury to the inferior dental nerve in the canal and its effect on the front teeth, and secondly the probability of sepsis. Bruhn, of Düsseldorf (as a result of coöperation of dental surgeon and surgeon in military orthopædic surgery), relieved the condition by resection of the mandible below the notch but above the inferior dental foramen by a subcutaneous osteotomy, and this operation has also been performed by Babcock in Philadelphia. In the case reported this method was chosen and Mr. Watkin first fitted cap splints to the jaws, packing the splint to lever the jaw into the best position as studied on models of the patient's bite, and the osteotomy was performed. After six weeks in the splints it was found that the upper posterior molars locked the bite and that the incisors did not meet. After extraction of these teeth and grinding down of some posterior teeth which had never met and been worn to the pattern of their opponents the patient was left with sixteen teeth in good occlusion. The patient was now able to eat satisfactorily. Photographs and models were shown and emphasis was laid on the advantage of the surgeon and dental surgeon coöperating from the start in deformities and fractures of the jaws.

HARVEIAN SOCIETY.

Streptococcal Infections.

A meeting of this Society was held at Paddington Town Hall on Feb. 20th, with Dr. P. **Montague Smith**, the President, in the chair.—Dr. C. **Bruce Perry** read the Buckston Browne Prize Essay. The problem of the streptococcus as a causal factor in disease, he said, had not yet been satisfactorily solved, and it was impossible to say whether the multifarious illnesses connected with streptococcal infection were entirely strain-specific or not. The recent work of Birkhaug and Small gave further support to the hyperergy hypothesis according to which a sensitised person was liable to react briskly to further doses of streptococcal infection. Dr. Perry thought the portal of entry, the condition of the patient, and the series of illnesses to which this individual had been previously subject played a large part in determining what type, if any, of chronic streptococcal illness he was likely to develop. Further research work could be more satisfactorily directed to the consideration of the patient's condition than to the identification and differentiation of the various types of streptococci. Focal sepsis itself did not seem to play a large part in this type of illness. There was no proof, even if a patient did recover after the removal of the focus, that such was the primary cause; for in all probability the improvement was due to the general improvement in the patient's resistance. Consequently, it was more important to consider his metabolic type, the illnesses from which he had previously suffered, and the way in which he reacted rather than to concentrate upon the type of organism with which he was infected.

Dr. R. **Cove-Smith** said he was entirely in agreement with Dr. Perry about the importance of the individual as compared with that of the organism. Absorption of toxic products lowered the resistance of the patient, thus leading to spread of local infection and involvement of other organs of the body. As a result of this spread from the primary focus, secondary lodgement might occur, and it was at this stage that focal sepsis became important; for where previous sensitisation had taken place, widespread results might follow. The work of Parish and Okell suggested that the various streptococcal infections were due essentially to the same species of bacteria. The pathological effect varied with certain factors, mainly quantitative, such as invasiveness and toxicity on the part of the strain, and local or general susceptibility on the part of the host. The chemical make-up and metabolic pattern of the patient were of manifest importance. Thus streptococcal infection which in a normal individual might give rise to a secondary anæmia, would tend to produce pernicious anæmia in those with defective bone-marrow, or subacute septic endocarditis in those with an incomplete endocardium and damaged heart valves. Apparently the main factors involved were: (1) The virulence of the organism. Hæmolytic streptococci tended to produce acute illness. (2) The amount of toxic absorption. (3) The resistance of the patient. It was upon this factor that the neutralisation of toxin depended. Consequently, endocrine deficiency, dietetic errors, disorders of metabolism and previous illness were of extreme importance in the development of chronic streptococcal illnesses.

Reviews and Notices of Books.

THE PROBLEM OF SLEEP.

Der Schlaf: Mitteilungen und Stellungnahme zum derzeitigen Stande des Schlafproblems. By Prof. PÖTZL, Prof. v. ECONOMO, Prof. PICK, Dozent Dr. MOLITOR, and Prof. STRASSER (all of Vienna). Edited by San-Rat. Dr. SARASON, Berlin. Munich: J. F. Lehmanns. 1929. Pp. 107. M.5.50.

IT is perhaps characteristic of present-day research that books and monographs dealing with a selected medical subject, touching different circles of study, or offering different aspects deserving attention, seem to be forthcoming in ever-increasing number. To decry team-work is out of date, if not reactionary; but there are times when we feel that the heart of a problem is not to be attained by skirmishes on its outskirts. To discover the route that leads to the core of the problem concerned is worth more than to explore neighbouring lines of investigation which may in the end prove to have led nowhere. Such thoughts are aroused by perusal of a learned symposium on the question of sleep, contributed to by distinguished authorities of the Vienna school, and dealing in the comprehensive German manner with its biology, physiology, pharmacology, and treatment. Sleep is discussed as an energic problem, as a psychical problem, as a problem in localisation, in circulation, in excitation, and so forth. All is very well done indeed, and for those who are already oriented in the subject the various points of view of the writers prove illuminating and instructive. But we miss a synthesis in the midst of so much analysis; we should have liked the editor to summarise arguments and set out conclusions. For example, since Prof. v. Economo draws attention to the fact that decerebrate animals and anencephalic monsters (lacking in part at least the optic thalamus) exhibit periodic change between waking and sleeping, we wish to know the bearing of this on Prof. Pötzl's general discussion of sleep as a question of the psyche. Reconciliation is wanted, and may indeed be apparent to the informed; but none the less it is missed from this work. Prof. v. Economo argues stoutly for the existence of sleep centres capable of anatomical (i.e., spatial) localisation, but yet is compelled to allow that not all disorders of sleep function can possibly be ascribed to them alone. Sleep cannot have its ultimate cause in the nervous system but only its regulation, and in fact only part of that.

The book is somewhat marred by an inordinate use of italics and italicised sentences.

PROGRESSIVE RELAXATION.

A Physiological and Clinical Investigation of Muscular States and their Significance in Psychology and Medical Practice. By EDMUND JACOBSON, A.M., Ph.D., M.D., the Physiological Laboratory, University of Chicago. University of Chicago Press. 1929. Pp. 428. 22*s.* 6*d.*

THE title of this book scarcely indicates its contents; if "progressive relaxation" smacks of the plausible therapeutist whose knowledge of the anatomy and physiology of the nervous system is minimal the reader will be most agreeably surprised by the thoroughly objective and experimental standpoint of its author. There is much more in these pages than a scientific technique for obtaining muscular rest; they range over many problems of the motor system, inclusive of muscle tonus, the neural regulation of muscular contraction, the relation of the emotions to the somatic and visceral musculature, and others of abiding interest to the practising neurologist.

Dr. Jacobson supplies a detailed description of his methods for enabling the subject to relax properly and completely—so absolutely, indeed, that he has on several occasions been able to demonstrate abolition of the knee-jerk, although the person experimented with is not in point of fact asleep. This is clearly a phenomenon of considerable significance, since it appears to prove that little by little (for the procedure takes a certain time) the musculature can be so emptied of tone by voluntary inhibition that reflectivity is temporarily interrupted. It throws light on the loss of the knee-jerk in sleep, in narcolepsy in cataplexy, and compels the student of the question to revise current conceptions of the relation of symptoms to lesions. For here is loss of the reflex as pronounced as if the dorsal columns of the cord were sclerosed. Believing that the commonplace complaint of the nervous and neurasthenic patient that he is in a "state of nervous tension" deserves acceptance at its face value, Dr. Jacobson applies his technique in such cases with a view to counteracting, or doing away with, certain activities which place an undue tax on the organism. He believes the method possesses obvious advantages over drug therapy, and illustrates its appropriateness by a series of cases of acute and chronic neuromuscular hypertension (worry, anxiety, restlessness, inability to concentrate, emotional imbalance, stuttering, compulsions, and psychasthenic syndromes). Judging by his reports, intensive rest of a thorough-going physiological kind merits full trial.

A good bibliography adds to the usefulness of a book which is distinguished throughout by its scientific setting and which reveals impressively the cautions and critical spirit of its writer.

PHYSIOLOGY.

Essentials of General Physiology. By ERIC PONDER, M.D. D.Sc., Professor of General Physiology, New York University. London: Longmans, Green and Co., Ltd. 1929. Pp. 497. 15*s.*

ALTHOUGH this book is primarily meant for medical students who have passed their first examinations in chemistry and physics, the author does not rely upon more than an elementary knowledge of these subjects, so that his book should be interesting and attractive to a wide circle. In the first five chapters the physico-chemical foundations on which physiology rests are discussed in a readable manner. The latter portion of the book deals with certain aspects of physiology—muscle and nerve, secretion, digestion, respiration, circulation—in general terms, theoretical discussions being avoided. The medical reader of these portions of the book will be conscious of a mild dissatisfaction, probably due to the deliberate bar against controversial matters. The book is, however, an excellent one on the whole. Minor points which call for criticism are the excessively small print used in the index and the almost complete lack of detailed references to individual work. The author has purposely refrained from mentioning individual investigators by name; in our view this is a mistake, for whether a piece of sound experimental work is old or new, it is always stimulating to read the individual worker's own account of the problems he has tackled and of the methods he has adopted to meet them.

Applied Physiology. Third edition. By SAMSON WRIGHT, M.D., M.R.C.P., Lecturer in Physiology, University of London, King's College. London: Humphrey Milford, Oxford University Press. 1929. Pp. 552. 18*s.*

IN the third edition of this book no changes of structure have been made, but accounts of new work have been included. Amongst the additions are sections on conditioned reflexes, chronaxie, the separation of pituitrin into two components, oxytocin and vasopressin, œstrin, Zondek and Aschheim's pregnancy test, and the modification in the structural formula attributed to glutathione.

At the present time when vast amounts of work are being poured out from laboratories all over the world it is becoming difficult to deal adequately with, and assess the value of, the drops that make up the stream of fresh investigation. Dr. Wright has, however, managed to note much new work, though some of the recent advances are dealt with rather briefly. For example, in the section on the ductless glands no mention is made of the recent production by T. F. Gallagher and L. C. McGee of active testicular extracts, or of the work of G. W. Corner on the corpus luteum, and his production of an active extract capable of replacing the ovary in early pregnancy. In the chapter on carbohydrate metabolism the cause of diabetic coma is ascribed principally to the accumulation of aceto-acetic acid in the blood. This belief is not now so confidently held as the reader of this account might be led to believe. The book is a fine piece of work, on which Dr. Wright deserves congratulation.

A System of Surgery.

Die Chirurgie. By Prof. Dr. M. Kirschner and Prof. Dr. O. Nordmann. Lief. 25. *Die Chirurgie des Gehirns und seiner Häute.* By Prof. Dr. Egan Ranzi, Innsbruck. *Die Chirurgie des Vegetativen Nerven-Systems.* By Prof. Dr. F. Bruning and Prof. Dr. O. Stahl. Berlin: Urban and Schwarzenberg. 1929. Pp. 608.

This section of Kirschner and Nordmann's large system of surgery achieves the high standard of performance which former volumes have led us to expect. It gives a sound, though not elaborate, account of brain surgery in which the different parts of the subject receive adequate attention. Prof. Ranzi has not described neurological diagnosis in great detail, since he regards this as the province of the specialist. His attitude towards the relation of surgery to neurology is hardly one to be encouraged, for history of this branch of work especially has shown that the surgeon has advanced here, as elsewhere, in proportion as he has become more medically and physiologically minded. Prof. Brüning and Prof. Stahl have dealt successfully with a very difficult subject, steering clear of unwarranted enthusiasms and yet not withholding information the reliability and value of which only future experience can determine. The benefits that can be expected from periarterial sympathectomy, and such experimental operations as those of John Irvine Hunter and N. B. Royle are set out with admirable judgment. Altogether the volume is well worth study.

A Manual of Mendelism.

Second edition. By James Wilson, M.A., B.Sc. London: A. and C. Black. 1929. Pp. 143. 4*s.* 6*d.*

An admirably clear and cheap account of Mendelism intended primarily for agricultural students and dealing mostly with stock breeding. By some fad of the author, there is no mention of chromosomes or genes; it is interesting to see that the facts can be so well stated in terms of themselves, but the confirmation of genetics and cytology by one another has surely been one of the most impressive achievements of modern biology, of which students should at least hear a little. However, no one who wants to know the principles of Mendelian inheritance can do better than to get this book, which contains a good deal more information than its number of pages may suggest.

The Chromosomes in Man.

Sex and Somatic. By Herbert M. Evans and Olive Swezy. University of California Press. 1929. With 11 plates. Pp. 41. 6*s.* 9*d.*

The difficulties inherent in all investigations into the character and behaviour of chromosomes have hitherto made the subject to some extent inaccessible to the cautious worker in other fields; he has felt that only the specialist, with an intimate knowledge of the technique of the processes involved, was in a position to judge of the probable accuracy of the facts so freely quoted in the literature of heredity. This hesitancy has been fostered by the conflicting evidence which is inevitable in the early days of a new line of investigation, whilst methods are being tested and technique is being developed and elaborated. This study by Evans and Swezy will do much to bring the subject more within the scope of other workers. The authors are to be congratulated on the clearness of their description and on the critical attitude they have maintained throughout with regard to their experiments; the very illuminating plates and illustrations, too, are of great assistance in giving a clear conception of the work and its great possibilities. There is evidently a vast field awaiting exploration. All original measurements are given, to the great advantage of those who desire to judge for themselves what is the significance of conclusions drawn from them.

Several years have been devoted by the authors to the preparation of this memoir; they should be rewarded by a widespread appreciation of its value.

History of Medicine.

The Canon of Medicine of Avicenna. Incorporating a Translation of the First Book. By O. Cameron Gruner, M.D. Lond. London: Luzac and Co. 1930. Pp. 612. £2 2*s.*

All interested in the history of medicine will be grateful to Dr. Gruner for this informing and beautifully produced book, and no one can read his description of the relations between the Canon of Avicenna and modern thought, or his exposition of the knowledge presented by the Canon, without appreciating that the work has been one of intensely applied labour and that the labour was one of love.

In the history of medicine the tenets of Islam played a highly important part which this book compels the reader to recognise. As far as our science is represented in literature, Hippocrates was the founder of medicine, the Alexandrian School as typified by Erasistratus and Herophilus made valuable additions, and Galen, writing in Greek and summing up for Rome the Greek wisdom, accepted the precepts and dogmas of Hippocrates; and although more recent knowledge tempted Galen to make additions, his new learning seduced him into the development of theories and hypotheses which he was unable to support. Galen died when the Roman Empire was at the height of its splendour, and on the Dark Ages which followed Roman scientific research made no impression, and at best its impetus was never a strong one. The history of medicine stopped short with the barbarian invasions of the far-flung Roman boundaries, and such culture as survived fell into the hands of the Christian Church which was perpetually in conflict with itself. It is in the Islamic revolt from Christianity that the line of progress is to be found. Mahomet was born in A.D. 570 and was certainly aware of the Christian writings for he borrowed from them. The rapid spread of Mohammedanism over the parts of Asia and Africa contiguous to Europe, and various successful military invasions, brought the culture of the Arabians, as it developed, into touch with Western peoples. During the long period when little or nothing was added to the scientific wisdom of a Europe represented by the bewildered Roman provinces, transformed and rearranged under waves of invasion, the Arabians kept medical knowledge from complete submersion. Haroun al Raschid, who synchronised approximately in English history with Alfred the Great, founded a hospital and medical school in Bagdad, and between A.D. 850 and A.D. 927 three Arabian physicians made their indelible marks, Rhazes, Abbas, and Avicenna, of whom the last was the greatest, and for some four centuries his Canon was regarded as containing infallible doctrine.

Dr. Gruner's treatise on the Canon incorporates a translation of the First Book, and in this translation we can see what a mass of learning was brought together by the famous Arab, and can forgive as well as be amused at the elaborate therapeutics, because of the really philosophical insight that characterises the whole work. "The place for Avicenna in modern thought," says Dr. Gruner, "is gained when it is agreed that he shall be viewed as one who entered this world entrusted with a mission independently to express for that age, by means of those various tools which he then found in it, the wisdom which is unchanging and impersonal." This sentence contains the gist of a wise chapter on the nature of the knowledge presented by the Canon, and of a further section pointing out the basic difference between the Canon and modern medicine. The Canon treats of speculative medicine on the grounds that the whole of the Universe is the manifestation of the universal principles of life acting through the instrument of certain forms. Modern medicine strives to obtain the rank of a positive science, and in doing so is compelled to exclude from its fundamental principles philosophical speculations, which constitute the very essence of the matter for Avicenna. Dr. Gruner summarises for us the conceptions known to modern medicine but not to Avicenna, as well as the knowledge common to Avicenna and modern medicine, and concludes his prefatory remarks with the following passage: "In the intention of this work, then, there comes into consideration that greater Art of Medicine—not an ethical Hippocratic ideal, but something of the divine—an Art as real to Avicenna, philosopher, poet, musician, the worker among the great and the small, aware of the dramatic in Life as it should be to us. So we step out of the world of the modern critic, the scholar, and the medical historian, indeed of modern medicine itself, into one in which we stand, as it were, hand in hand, with the great Master of the East—almost with his very eyes gazing upon and scrutinising this ever open book of Life of ours—divested of the false notions of 'progress' and 'time.'" Read in the spirit which the learned translator and commentator thus suggests to be the right one, the whole Canon becomes of absorbing interest, while the modernity of some of the injunctions is all the more stimulating by their proximity to other injunctions, due to the exaltation of traditional rumour into exact experience. Throughout the translation Dr. Gruner makes profuse and wise reflections, when the references to the far-ranging literature referred to are carefully given.

The translation is made from the Latin version, signal help being acknowledged by the author, in respect of the Arabic, Persian, and Chinese essential to his purposes, from the School of Oriental Studies, London Institution (University of London).

Le Adiposità Patologiche.

By Prof. Giovanni Poggio, of the Institute of Clinical Medicine, University of Genoa. Bologna: L. Capelli. 1929. Pp. 315. L.40.

This work has a preface by Nicola Pende, professor of clinical medicine at Genoa, who praises it as a painstaking treatise compiled with great competence and diligence. In his view the conclusions arrived at represent the greatest possible progress in the elucidation of a disease which shortens the life of a very large number of people; there can be no doubt of the painstaking labour which has gone to their compilation.

In the chapter on the pathogenesis of adiposity the author sums up the results of his researches. Acquired adiposity, that which is due to idleness or over-feeding, is, in a large measure, consequent on a neuro-endocrine habit already established in the individual, and some cases are determined by acquired lesions of the thyroid. The adipogenetic factor is not always limited to the one endocrine gland principally affected, but may result from the sum total of functional disorders introduced into the neuro-hormonic equilibrium by the functional defect of the organ primarily implicated. The pituitary is a frequent cause of acquired adiposity with well-marked differential characters which are especially prevalent during the first ten years of life. A prevalent pathogenic factor also is the posterior pituitary lobe which regulates the mechanism of fat metabolism. The origin of some adiposities in which the genital gland is often solely incriminated is still uncertain, but hypogenital or agenital adiposity presents clinical features easily appreciable and useful for differential diagnosis. But the tendency to fat in the hypogenital or in young castrates does not run parallel with an habitual or constant elimination of oxidation—the two factors being entirely dissociated; the cause is really a concurrent hypofunction of the thyroid or a functional recrudescence of the thymus. This explains why adiposity is not found in some cases of hypogenitalism and castration; individual factors and endocrine interaction regulate the reaction of each organism to the genital functional suppression.

Prof. Poggio found in his cases that the respiratory exchange while fasting showed no fixed behaviour, and he thus excludes the possibility of an interdependent relation between diminution of oxidation and adiposity of thyroid origin. The same may be said of the specific caloric value of foods. As regards the pathogenesis of constitutional adiposity, there is a large group of adiposities, prevalent in youth and due to functional inadequacy of some of the endocrine glands (pituitary, thyroid, genital, and suprarenal) which induce certain conditions in the regulation of caloric exchange. There is a group which is dependent on hyperfunction or hyperplasia of other endocrine glands such as the suprarenal cortex, pancreas, and genitals in man and the corpus luteum and mammæ in women; and further, there are adiposities in which the endocrine factor plays a less relevant part and where the constitutional disorder is confined to the cellulo-adipose tissue—lipotropism or lipophilia. The most interesting chapter in the book is devoted to the clinical varieties of adiposity, including Dercum's disease, the syndrome of Launois and Bensaude, and neurolipomatosis dolorosa of Recklinghausen. Therapeutic measures receive rather scanty treatment. In a bibliography of 426 references, chiefly from German and Italian sources, British names are conspicuously absent, showing perhaps that the subject of adiposity has not received so much attention from scientists in this country as from those abroad.

A Manual of Pharmacology.

Seventh edition. By Walter E. Dixon, M.A., M.D., B.S., B.Sc., D.P.H., F.R.S., Sometime Professor of Materia Medica and Pharmacology at King's College, London; Assessor to the Regius Professor of Physic, and Reader in Pharmacology, Cambridge. London: Edward Arnold and Co. 1929. Pp. 486. 18s.

For the benefit of those who are approaching the subject of pharmacology for the first time we may state that Dixon's text-book is recognised as a standard work on the subject, and that the name and reputation of the author are guarantees that any new addition will present the most up-to-date information, carefully considered and cogently expressed. The book contains not only a complete account of the action and uses of drugs, but deals with a number of allied subjects such as antitoxic sera, vaccines, radiotherapy, and radium. For a generation this work has held its place as one of the best of the text-books of pharmacology, and this seventh edition is not likely to be less popular than its predecessors.

A Study of Tuberculous Cavities.

Étude clinique et radiologique des cavernes tuberculeuses. By Dr. Jaquerod (Leysin). Paris: Masson et Cie. Fr.16.

This monograph, coming from the Leysin clinic, is of particular interest. It deals with those circular shadows which occur in the lung fields and look so convincingly like cavities. There are only ten pages of letterpress and illustrations of some 40 cases. The author discusses the interpretation of these circular shadows from the radiological and clinical aspects, and classifies true cavitation into three degrees. He shows that all three degrees may undergo a process of healing, and their radiological appearances disappear. There are some good examples of pseudocavity shadows among the illustrations, all of which are extremely well reproduced and are accompanied by excellent descriptions which amplify the text.

This is an important monograph, and throws new light on the interpretation of these difficult shadows. It should be in the hands of all those interested in the radiological investigation of the lungs, and particularly those who are doing sanatorium and tuberculosis work. It is very well produced and reasonable in price.

DEFINITION OF DRUGS FOR THE PURPOSES OF MEDICAL BENEFIT.

REPORT OF THE ADVISORY COMMITTEE.

THE Advisory Committee on the Definition of Drugs for the Purposes of Medical Benefit, whose second report was briefly summarised in our columns last week, was appointed by the then Minister of Health, in February, 1929, and consisted of Dr. Dudley G. Greenfield (*Chairman*), Mr. T. Allsop, Dr. J. J. Day, Sir Walter M. Fletcher, F.R.S., Mr. J. E. French, M.P.S., Dr. A. F. Heald, Mr. W. Gill Hodgson, Dr. E. Lewis Lilley, Mr. F. Llewellyn-Jones (who resigned and was replaced by Mr. J. E. Tomley, in November, 1929), Mr. G. A. Mallinson, Mr. Edwin Potts, Mr. Philip F. Rowsell, F.C.S., Mr. Thomas Tickle, F.I.C., with Miss E. M. R. Russell-Smith, of the Ministry of Health, as Secretary.

Their terms of reference included the distribution of 165 substances and preparations submitted to them into certain categories, depending on whether the particular substance of preparation was, in their view (*a*) never a drug, (*b*) always a drug, (*c*) sometimes a drug. They concluded that this classification was too simple, since certain preparations, though admittedly drugs or medicines which in appropriate circumstances should be supplied to insured persons at the cost of the Chemists' Fund, yet, from their nature and cost should only in exceptional circumstances be prescribed in preference to other substances and preparations of reputed analogous therapeutic effect. They found it convenient, therefore, to allocate the substances and preparations referred to them among six different categories—namely, Classes A, B1, B2, B3, C1, and C2.

Never a Drug.

Class A contains substances and preparations which, in the opinion of the Committee, are never drugs. In this category are placed :—

Acidophilus milk, albulactin, Allenbury's food, ambrosia, arrowroot, Benger's food, bovinine meat juice, bovril, Bragg's charcoal biscuits, Brand's essences, brandy, bulgarlac, calves' foot jelly, cane sugar, Carnrick's peptonoids, casein food, casumen, ceregen, cerolia cream, champagne, chymol, coffee, diabetic bread and biscuits, energen bread and biscuits, glaxo, glaxovo, gluten bread, glyco-lactophos, herogen, Horlick's milk, hi-g-ah tea, ice, instant postum, iodised salt, lactic milk, lacto-dextrin, lactogen, lactose, lemco, mabela, marmite, meat extracts (other than liver extracts), meat juices, Mellin's food, melovol, midolia biscuits, Muller's nutrient, new-promonta, numol, nutrient suppositories, oatmeal, ovaltine, oxo, panopepton, pearl barley, peptonising powders, plasmon, plasmon oats, Robinson's barley and groats, roboleine, saccharin tablets, sanaphos, sanatogen, Savory and Moore's foods, sherry, somatose, tonagen, Torbet's lactic oats, Valentine's meat juice, valkasa, vibrona, vigoral, virol, virol and milk, vitafer, vitagen, vitalia meat juice, zomogen tonic food.

Always a Drug.

Class B1 would contain those substances and preparations which were, in the opinion of the Committee, always drugs, and could unquestionably properly be supplied to insured persons at the cost of the Chemists' Fund. It will, however, be observed that none of the substances and preparations so far referred for consideration are placed in this class.

Class B2 contains substances and preparations which are always drugs, but an insurance practitioner might reasonably be called upon to justify the prescribing of the substances and preparations in this class in the event of an investigation of his prescribing. Examples are :—

Agar-agar, Angier's emulsion, antiphlogistine, boroglyceride, californian syrup of figs, ergo apiol, Fellow's syrup, formamint tablets, glycothymoline, Heath and Heather's herbs, liver extracts, metatone.

Class B3 contains proprietary substances and preparations which are alleged to be drugs or medicines but of which the composition is undisclosed. The Committee consider that the prescribing of such substances and preparations is most undesirable, and hold that only the most exceptional circumstances could justify a practitioner in prescribing them. Examples are :—

Alkia saltrates, Andrew's liver salt, antigermis, antigermis (liquid), Beecham's pills, bisurated magnesia, Cassell's tablets, cicfa tablets, cuticura ointment, dermisol ointment, Eno's fruit salt, feen-a-mint, felsol powders, germolene ointment, Gibb's insectol cream, guycose, Hair's asthma cure, Himrod's asthma cure, intubine, irocose, kruschen salts, miol, " Odds on " liniment, pepsencia, phosferine and phosferine tablets, phyllosan, reudel bath saltrates, salvitæ, sulphaqua bath charges, tamar indien laxative lozenges, taxol tablets, Tidman's sea salt, vinculin.

Sometimes a Drug.

Class C1 and *Class C2* contain substances and preparations which may be, but are not always, drugs or medicines for the purposes of medical benefit. (*a*) *Class C1* contains substances such as cod-liver oil, extract of malt and non-proprietary preparations, and combinations of these substances. While it may be argued that such substances should technically be classified as foods, and not as drugs, yet the common acceptance and usage at the present time necessitate their being recognised as drugs in many of the cases in which they are prescribed. The Committee consider, however, that these substances and preparations are occasionally prescribed in circumstances which would render it difficult to establish that their use was therapeutic rather than alimentary. (*b*) *Class C2* contains substances and preparations, the prescribing of which by insurance practitioners is, in the opinion of the Committee, justifiable only in special circumstances. Among other substances and preparations included in Class C2 are proprietary preparations of cod-liver oil, or of malt extract, or of both combined. Examples are :—

Allen and Hanbury's malt and oil, antiseptic soaps, bemax, bynin, bynogen, byno preparations, bynol, byno and oil, bynotone, Cheltenham spa water, cod-liver oil tablets, cream of malt, cuticura soap, glovo cod-liver oil tablets, hæmatogen, hazeline cream, jecomalt, Jeyes' fluid, Kepler's maltand oil, lactagol, lactomaltine, maltine, maltine and oil, metagen, omnevit, ostelin, ostelin preparations, radio malt, radiostol, radiostoleum, resinol soap, Scott's emulsion, virolax, vitamalt, vitamine malt, vitamogen, vitmar, Wander's malt and oil, Wander's malt extract c. hæmoglobin, yeast-vite tablets.

The Committee note the possibility that information may become available at some future date which might cause them to revise their opinion of some or all of the preparations included in Class C2, but consider that for the present this classification is appropriate.

Some Special Cases.

They think it desirable to amplify their reasons for including the following substances or preparations in a particular category.

Peptonising Powders. (*Class A*).—They consider that the ordering of peptonising powders as such definitely assigns them to the position of adjuncts in the preparation, external to the body, of foods of a particular character, and consequently precludes them from being regarded as drugs or medicines for the purposes of medical benefit. They would, however, regard as drugs the components of peptonising powders, e.g., pepsin, &c., when ordered by name in definite quantities to be taken internally in prescribed doses.

Liver Extracts. (*Class B2.*)—These substances are known to exert definite therapeutic effects in certain pathogenic conditions, notably pernicious anæmia, and have therefore been included in the category of drugs or medicines. Though these effects can be obtained by the consumption of animal liver, the human digestive system may be unable to deal with the quantity of liver necessary to produce the required therapeutic effects; where this is the case, the exhibition of concentrated extracts of liver substance is essential for satisfactory treatment. The Committee consider that a standard should be fixed for these extracts.

Medicinal Herbs. (*Class B2.*)—The Committee consider that the prescribing of these crude substances rather than medicinal preparations thereof would only be justifiable in exceptional circumstances.

Antiseptic and Medicated Soaps. (*Class C2.*)—Though these substances are occasionally prescribed by practitioners of repute, the Committee have considerable hesitation in regarding them as substances which might be drugs; these soaps must be regarded as cosmetics save in exceptional circumstances.

Spa and Mineral Waters.—The Committee have experienced some difficulty in the classification of these substances, as they vary in composition from a weak saline solution suitable for the dinner table to a strong saline solution only suitable for administration as a drug. Each case must therefore be considered on its merits. Where an alleged spa water is of unknown composition, however, they would unhesitatingly place it in Class B3.

Disinfectants.—When ordered as such clearly cannot be regarded as drugs for the purposes of medical benefit, but disinfectants ordered by name in definite quantities with directions for therapeutic use internally or externally would be regarded as drugs.

Suggested Regulation.

The Committee conclude that it would be undesirable to attempt to regulate the present position by amendment to the existing regulations, and therefore recommend that a new regulation shall be made in the general form of the following draft.

1. An Insurance Committee shall have power to recover from a practitioner by deduction from his remuneration or otherwise the cost of any substance or article prescribed by the practitioner on the official form which is not a drug or medicine, or an appliance included in the Second Schedule to the principal Regulations, and shall pay the amount so recovered into the Chemists' Fund.

2. If any question arises as to the recovery of any sums under the preceding Article, or if any question arises in the course of an investigation, or otherwise, for determination whether a substance or preparation is one which should be ordered for or supplied to an insured person, the Committee shall refer the matter to the Panel Committee. If the Panel Committee and the Committee disagree, the matter shall be submitted to Referees appointed under this Article for decision in such summary manner as, subject to any rules made by the Minister in that behalf, may be directed by the Minister; and the decision of those Referees, given after hearing such parties and taking such evidence, if any, as they think just, shall be final.

For the purpose of giving effect to this Article the Minister shall, upon any such question arising, nominate as Referees two practitioners (who shall be selected from any panel of practitioners set up by the Minister for the purpose, or if no such panel exists, from among practitioners in actual practice) and one barrister-at-law or solicitor in actual practice.

The Referees may decide any question coming before them by a majority, but subject as aforesaid, their procedure shall be such as they may from time to time determine.

If on any question referred to the Panel Committee under this Article the Committee and the Panel Committee are agreed, the Committee shall report the matter to the Minister, and the Minister may, if he thinks fit, refer the question for decision to Referees in the manner provided in this Article, and the foregoing provisions of this Article shall apply accordingly.

The Committee hold that the Insurance Committee should take action under paragraph 1 of the suggested regulation when the substance prescribed (*a*) is included in a list, issued by the Insurance Committee to the insurance practitioner, of substances considered by the Insurance Committee never to be drugs, or (*b*) is adjudged by the Panel Committee in the course of an investigation of prescribing or otherwise not to be a drug in the circumstances in which it has been prescribed, or (*c*) is of such a nature that obviously it cannot reasonably be considered to be a drug.

Procedure.

The position relating to the prescribing of substances which the Insurance Committee had decided never to be drugs would be as follows: (1) The insurance practitioner would be surcharged the cost of the substance so prescribed, but would have a right of appeal to referees. (2) The insurance chemist would be required to dispense the prescription, and would receive payment. (3) The Insurance Committee would take action under the proposed regulation. (4) The insured person would have a right of complaint against the insurance practitioner under Article 32 of the Medical Benefit Regulations, 1928, for refusing to prescribe an alleged drug.

As regards substances which the Insurance Committee had decided to be sometimes drugs and sometimes not drugs, the prescribing of such substances should, in the first instance, be investigated by the Panel Committee under Article 42 of the Medical Benefit Regulations, 1928. If it was decided that the whole or any proportion of the substances prescribed were not drugs in the case in question, the Insurance Committee could recover the cost thereof from the practitioner concerned, the position of the chemist and the insured person being the same as in connexion with substances which the Insurance Committee had decided never to be drugs.

MEDICINE AND THE LAW.

Heavy Sentences for Criminal Abortion.

THE police authorities notoriously find it difficult to bring cases of criminal abortion to justice: when, however, the criminals are caught and convicted, judges inflict stern sentences. Recently, at the Central Criminal Court, Mr. Justice Talbot sentenced to five years' penal servitude a man of 43, described as a herbalist, who pleaded guilty to a charge of supplying noxious things to a number of women knowing they were to be used for the purpose of procuring miscarriage. Prosecuting counsel said that the accused had no medical knowledge: he had been a stoker in the Navy. His shop in Notting Hill Gate was in such an appalling state of dirt that it was a danger to the community for that reason alone. The judge observed that the prisoner's conduct was not only illegal in the highest degree but also dangerous to health. In another case a few days later Mr. Justice Avory inflicted a sentence of seven years' penal servitude at Bristol Assizes in respect of illegal operations and other illegal acts charged as having been committed at Bath, Bristol, Bridgwater, Cardiff, and London. The prisoner made the somewhat impudent defence that what he did was merely a pretence intended to satisfy the women that they were having treatment. There were allegations also of conversion of money and of indecent assault; the judge stated he had never met a case containing so many circumstances of aggravation. In the Central Criminal Court case (first mentioned above) it was suggested on the prisoner's behalf, in mitigation of sentence, that he had acted in ignorance of the law. The severity of these sentences may serve to remove such ignorance, if it exists.

OCCUPATION IN HOSPITAL.—The New York City Visiting Committee, a voluntary body, have formed a Hospital Occupation Committee which devotes itself to the promotion of occupational therapy. In the Bellevue Hospital children carve wooden rabbits in order to manipulate fractured wrist-bones which are mending; other patients work objects resembling spinning wheels which are really treadles for restoring strength to injured ankles. Wool, raffia, leather, and beads are distributed with instructions how to make pretty things of them. The members of the Occupation Committee act as voluntary helpers to the regular staff of occupational therapy officers, giving to the work such time as they can spare.

THE LANCET.

LONDON: SATURDAY, MARCH 1, 1930.

CENTRAL CLINICS FOR RHEUMATISM.

THE Red Cross Clinic for the treatment of rheumatism in London was opened early this week by the QUEEN; a little later than had been planned but yet at a singularly appropriate time, for it is in February that the constellation of cold, wet, dark, mist and northern latitude brings to a head the disability from chronic rheumatic disorders which cloud the lives of middle-aged people and especially those of the working classes. It is a story too often told to need repetition here what is the extent of this disability in terms of earning capacity, of wasted insurance funds, and of sheer human misery. The realisation of this first central clinic goes back ten years to the granting of a supplementary charter to the British Red Cross which enabled it to expand its services from the needs of war to those of peace. Five years ago, largely owing to the exertions of Dr. FORTESCUE FOX, the first international conference on industrial rheumatism was held in London, and since that time the official organisations of workers have gradually come to realise that timely expenditure on the relief of rheumatic disabilities at an early stage saves a bigger outlay later and that it would pay approved societies to run their own hostels at spas and to contribute freely to the cost of treatment of insured patients. This liberty has long existed abroad, and the Minister of Health has given leave now to our own societies to pay out of their funds a capitation rate to cover the fees of their members who attend for treatment.

It is Sir ARTHUR STANLEY'S hope, as chairman of Red Cross executive, to establish a chain of such clinics up and down the country, especially in the great industrial areas. Some thirty Red Cross clinics which continued active after the war will no doubt be included in the scheme, but it is in no way the intention of the promoters to limit the scope of these central clinics, and Mr. R. H. P. ORDE, speaking for the Central Bureau of Hospital Information, has definitely laid down the principle that advantage should be taken of existing facilities for the setting up of central clinics. In some places they should be associated with spas; in others with voluntary hospitals; in others again with municipal establishments. At present in London the Kensington and Hackney Red Cross clinics already give some rheumatic treatment, but the new clinic in Peto-place, as the report on p. 480 shows, is the first to be fully equipped with bathing accommodation. Although the clinic has no actual association with the existing spas in this country, their medical officers have coöperated generously in its inception, both by advice and demonstration, as well as in the training of personnel. The neighbouring Orthopædic Hospital in Great Portland-street has also placed its X ray installation at the disposal of the clinic, and its surgeons are prepared to undertake whatever orthopædic work may be necessary.

Although, as we have said, the Peto-place clinic is first in the field in London it is only just the first, for the Bermondsey Borough Council has decided to establish a clinic to treat chronic rheumatism and rheumatoid arthritis and has purchased a site for the purpose in the Tower Bridge-road at a cost of £11,000. Plans and estimates for building and equipment at a further cost of £94,000 have been adopted and passed by the council, whose intention it is to instal the most recent electrotherapeutic, physiotherapeutic, and hydrotherapeutic appliances. The story of this undertaking is of some interest. In the first instance the London County Council declined to advance a loan, on the ground that under the new Local Government Act the County Council itself was the proper authority to provide treatment of this kind, but after appeal to the Ministry of Health the loan has now been sanctioned. Before initiating the scheme the Borough Council ascertained from the authorities at Guy's Hospital that accommodation was not available there now, nor likely in the future, for treating chronic rheumatism on any large scale. It is stated that there are between 7000 and 8000 cases of chronic arthritis alone in the Borough of Bermondsey, most of them at present unable to obtain even palliative treatment.

◆

MUNICIPAL HOUSES.

OVERCROWDING in slum areas affects the health of the race as a whole, since no adequate protection against epidemic diseases can be offered while overcrowding continues. Public health schemes are seriously handicapped, and children living in slums cannot attain the best possible health and development. In practice, the problem resolves itself into one of child welfare; little is to be gained by uprooting old people from an environment in which they have spent their whole lives, but, with children, removal to better surroundings may make an enormous difference to mental as well as physical development. Overcrowding in this country is still very common, although it receives, perhaps, more serious attention here than anywhere else in the world. The municipal houses, which were to have provided accommodation for those for whom private enterprise does not cater, have, in practice, been occupied by those who could very well afford other quarters. The rents of these houses, though only 12*s.* or 14*s.* a week, are yet too high for the average labourer with a large family. Such tenants are inclined, not unnaturally, to feed their children before paying the rent, and are therefore unsatisfactory from the landlord's point of view. The unfortunate correlation between poverty and fecundity is well known, and the two establish a vicious circle which confines the labourer and his children to the slums.

Tuberculosis officers are continually faced with recurrence of disease in patients who return from sanatoriums to overcrowded areas; if it were possible for these patients to return to municipal houses, set in open spaces, their chance of continued health would be greatly increased, and the whole community would be benefited. At present the order in which applications for municipal houses are considered is as follows: married ex-Service men with families; married ex-Service men without families; ex-Service men intending marriage; married couples (not ex-Service) with families; married persons without families; persons intending marriage; others. This scheme allows no special consideration for sick persons, and the medical officer of health is not consulted when tenants are chosen. Dr. V. T. THIERENS, speaking at a meeting of the Society of Medical Officers of Health on Feb. 21st, suggested that the public health authorities of a district should take over about thirty council houses each year and use them for the accommodation of consumptives or other persons in especial need of a good environment; but the primary object of building municipal houses, after all, should be the removal of children from the slums. Dr. C. KILLICK MILLARD, speaking at the same meeting, proposed a system of rebates on rent for parents with large families. This system would entail a universal increase of 1*s.* 6*d.* per week on the normal rent, but with rents well below the economic standard this would probably be accepted readily. Families should then receive a rebate of 1*s.* 6*d.* per week for each of the first three children and of 1*s.* a week for each subsequent child. As the children left school the individual rebates would cease automatically, and be replaced after six months by a child-lodger tax of 1*s.* per head. To take an example, a couple with six children of school age would take a house of which the normal rent was 11*s.*, but which, with the initial increment, became 12*s.* 6*d.* During the time all the children were at school the rent would be 5*s.* per week; it would rise to 18*s.* 6*d.* when they had all left school, and fall to 12*s.* 6*d.* when they were all married or left home. The chief disadvantage of such a system is the danger, unless the corporation owns all the houses in the district, of all the municipal houses being occupied by tenants with large dependent families. A similar system is employed at Welwyn, but the rebate of 6*d.* per head is insufficient to make the scheme effective.

Much has been said against reconditioning of houses as a means of providing accommodation, and where this is undertaken in preference to building new houses it is probably a mistake. Dr. A. STUART HEBBLETHWAITE, medical officer of health for Sunderland, considers that reconditioning, though undesirable, is necessary, since few authorities have built sufficiently to avoid it. While the housing problem is so acute, reconditioning can be carried on at the same time as building, and to good purpose. If a five-roomed house is worth only £100 in the open market, and it can be put in order for £200, the expenditure is justified, since it will house five families at £40 per couple, and accommodation could not be obtained so cheaply in any other way. Where relatively expensive municipal houses are occupied by the labourers for whom they were intended, there is a serious danger that the tenants will economise on food to pay the rent. These are "good tenants" from the point of view of the corporation, but it is no economy to take a child from a slum if he is short of food in his new environment. Dr. C. LEONARD WILLIAMS, medical officer of health for Barking, believes that statistics showing milk bills of families before and after occupying these houses would give an indication of a fall in the standard of living.

The chaotic state of modern London might have been avoided had Sir CHRISTOPHER WREN been suffered to complete his plans for rebuilding after the Great Fire of 1666. Municipal houses, with all their disadvantages, are a step towards solution of the housing problem, but not as at present administered. The medical officer of health should share in deciding the tenancy; and, until a better system presents itself, rent rebates seem to offer the speediest means of removing our slum children to a better environment.

INFECTIVITY AND VIRULENCE.

A DISEASE may be highly virulent like imported small-pox or it may be highly infective like the common cold; it is fortunate for humanity that it is not often both. Epidemic disease has been described as a resultant rather than an entity: the result of an interaction between two opposite forces, the infecting agent and its host. Each time small-pox has reached us recently from abroad it has given rise to a set of cases of serious disease with a high mortality-rate, the factor of individual resistance has been wiped out by the virulence of the strain introduced, but it is remarkable how limited the epidemic has remained. A generation ago it was the generally accepted view, especially in relation to scarlet fever, that a mild case of a specific fever was equal in infectivity to a severe case, and when communicated to another person could give rise to severe and even fatal disease, but that the susceptibility of the population attacked was affected by temporary causes such as climate and dietary change, or by more subtle factors very hard to determine or estimate even by the skilful collection and treatment of data. Since that time we have learned means for determining human susceptibility which doubtless should in time throw light on such changes in resistance. Thanks to SCHICK and the DICKS, we can ascertain individual susceptibility to diphtheria and scarlet fever, and by means of their tests the conclusions reached by epidemiologists have been fortified in some cases, modified in others. It was the prevailing view that an outbreak of scarlet fever, largely a disease of the poor, came to an end because all those susceptible to the disease had been attacked; and in the main this has been verified by the Dick reaction. Epidemiology suggests that the relative insusceptibility of the Japanese to scarlet fever is due to a general immunity resulting from previous widespread epidemics, and the attack-rate, although still low in Japan, has shown an upward tendency during the last few years. The use of the Dick test by LAMY in Paris in 1926 led him to infer that immunity is conferred not only by an actual attack but by mere contact with the scarlet fever organism—a view long been held in regard to diphtheria.

In the last 30 years the attack-rate of scarlet fever has diminished in Western Europe, the case-mortality decreasing at the same time; but in Soviet Russia, Poland, and Roumania prevalence is increasing, while the case-mortality remains high; in Roumania it reaches nearly 200 per 1000. Moreover, in spite of all the preventive measures taken in the United States of America the prevalence of scarlet fever is increasing there. The decline in Western Europe may in fact depend not so much on our preventive measures as on the mass immunity conferred especially on children by widespread epidemics in the past and on the improvement in the living conditions of the poorer classes. In diphtheria it is generally agreed that a gradual latent immunisation is taking place; in German-speaking circles the possibility has been canvassed of the same phenomenon occurring in measles, a disease of high infectivity. As a rule, measles when inadvertently introduced into a hospital ward rapidly spreads to all the occupants who have not had a previous attack, but Prof. R. FISCHL and his colleagues in Prague have met with instances where children, who had not had measles, when exposed to infection failed to contract the disease; this he associates with the unusual number of non-eruptive and abortive cases. Prof. C. Noeggerath similarly has found that of 81 children exposed to infection in the course of seven outbreaks about two-thirds (56) escaped; he inclined to explain this on the ground of insufficiently close contact. Other German pædiatrists regard measles as liable to periodic variations of severity, but not of infectivity.

Application of the same principles to small-pox is precarious but tempting in view of the wide incidence over the country for some years past of a mild form of the disease with such dramatic interludes as that of the *Tuscania*. The mild type is evidently far less infectious than the severe type was generally held to be. It is known, for instance, that patients with an exanthem of the mild type out on them have travelled in crowded trams without giving rise to other cases in the area. Belief in the high infectivity of the severe form of small-pox is traditional; Rhazes was of the opinion that no one who was exposed escaped it. In the eighteenth century German writers estimated that five-sixths of all the dwellers in the then known world were attacked. English experience confirms this; in 1730–31, of the 1636 inhabitants of Hastings 705 suffered from small-pox, of the 931 who escaped no less than 725 had marks of a previous attack. In 1752 Lettsom remarked that most children in London contracted small-pox before reaching their seventh year. No rank of life escaped; a son of James II. of England, his daughter, Queen Mary, and his grandson, the Duke of Gloucester all died of small-pox. But it seems that the mortality of the disease in the eighteenth century was not so great as has been supposed. From German records we learn that the virulence varied much in different epidemics and in the same epidemics in different towns; the case-mortality which averaged 12–15 per cent. might be anything between 30 and 1 per cent. Mention of the last figure raises a suspicion that what we now call alastrim was present now and again in Germany; that it was present in England at this time there is considerable evidence. In Germany the differences were attributed to meteorological influence; should this now raise a smile be it remembered that no less scientific an observer than Sir Leonard Rogers holds that low humidity favours, high humidity checks, the disease. In this country where mean temperature follows absolute humidity a cold winter and spring would tend to an increase of small-pox.

Few living practitioners have had much personal experience of the infectivity of the severe form of small-pox. Those who had the opportunity of running round after outbreaks in the decade 1900–10 certainly formed the impression that small-pox was very contagious, based on such incidents as the following. In the north of England a delirious seaman escaped from a port sanitary hospital and was eventually found lying unconscious in his night shirt in a street urinal in a poor residential quarter. A simultaneous, or almost simultaneous, onset of the disease occurred in a considerable number of men and women. The narrow width of the urinal and the comparatively short time the infectious man was there before being removed negatived the possibility of any large proportion of those attacked having come into close contact with the sufferer. Here obviously the infectivity was very great, but the same does not hold for last year's experience. There are inevitable loopholes in the system of surveillance of small-pox, and at least two of the contacts who left the *Tuscania* for their homes developed the disease without their presence in the area being known to the executive health officer, who was not in a position to warn persons in the environment to adopt the safeguard of vaccination or revaccination. Yet in the absence of administrative action there was no further spread of infection. Again, in another instance three members of a family—father, mother, and grown-up daughter, all in a poor vaccinal condition—visited a woman contact from the *Tuscania* during the week-end and on the Sunday the onset of the disease occurred; but no spread to the contacts took place. In point of fact no further cases occurred in any instance from such contacts. Two views of the degree of infectivity have been held: one that it is in proportion to the extent of the rash; the other that it is in proportion to the severity of the strain. While both these conceptions are probably true in the main, the *Tuscania* incident goes to show that there must be other factors. Similar evidence is forthcoming from the United States of America where late cases of small-pox have repeatedly been discovered in contact with a relatively unprotected community and few or no secondary cases have resulted. In 1921 a severe and fatal epidemic in Kansas City began to make itself felt in November, but investigation revealed that two groups of fatal hæmorrhagic cases—five in all—had occurred in two different parts of the city, the one in April, the other in June, and apparently there was no further spread from these. That hæmorrhagic cases are usually infective is shown by the frequency of infection among those who handle the dead body. There is no explanation ready-made to fit these circumstances. It was formerly held that in certain communicable diseases the passage of the virus through susceptible individuals caused a progressive increase in its virulence and lethal power in much the same way as animal passage may be used to exalt the virulence of an organism. Experimental evidence on the point is scanty, and Gins holds that severe small-pox becomes milder when passed from body to body. And although the work of Topley and Greenwood suggests that an increase in virulence of the infective agent may sometimes occur in the course of an epidemic, the examination of cultures isolated at the height of an epidemic has not as a rule shown them to have greater virulence than those isolated at an earlier stage. We may recall the speculation of Sobernheim that the repeated passage of the small-pox virus through the bodies of a population immunised by vaccination brings about weakening of the strain. The *Tuscania* strain, derived as it was from India, might be capable of infecting one or at most two generations of persons of the Western race. Finally, German writers adduce some evidence in favour of inherited immunity against small-pox from vaccinated parents.

A MEDICAL EDITOR

News has reached us of the sudden death on Feb. 17th of Julius Schwalbe, who for more than 30 years had edited the *Deutsche medizinische Wochenschrift*, recently in collaboration with Prof. R. von den Velden and Dr. P. Wolff. The D.m.W., as it is familiarly known, now in its fifty-sixth year, was one of the few medical journals of the world to persist under the conditions of 1914–18, and we can testify to the tact and ability with which it was carried on through that troublous time. Although containing much less editorial matter than journals of similar scope in other countries, the D.m.W. throughout has borne the impress of Dr. Schwalbe's personality and genius for detail. His other undertakings were equally popular, the Outline of Special Pathology and Therapy, which first appeared in 1892, went through many editions and has been translated into several European languages; a large proportion of German practitioners use as their daily guide the Handbook of Therapeutic Technique for Medical Practice which he edited and of which for quite a while a new edition was demanded almost every second year. Dr. Schwalbe was interested in the conditions of medical practice in other countries and brought out in several editions a guide to the regulations for admission. At one time also he edited a Year Book of Practical Medicine.

Annotations.

“Ne quid nimis.”

GAS AND SUICIDE.

THE steady and very striking increase in the number of deaths from the inhalation of domestic gas has caused considerable anxiety. In 1918 the figure was 295, of which 102 were ascribed to accidents and 193 to suicide. In 1928 there were no fewer than 1359 fatalities, of which 1191 were suicidal. It is obviously possible that a certain number of the 168 supposedly accidental deaths were really suicide, as in cases of doubt the coroner's jury will always take a sympathetic view. It is clear therefore that the increase is very largely, if not entirely, one of suicide. A factor that must be taken into consideration, of course, is the number of gas consumers; in 1920 there were seven and a half million consumers, while in 1928 the number had risen to nearly nine million. Attention has been called to the subject in America as well as in this country, and we published recently a summary of the report of the American Medical Association's Committee (THE LANCET, Feb. 8th, p. 320). Following close on this appears the report of the Departmental Committee appointed by the President of the Board of Trade.[1] This Committee comes to the conclusion that the number of accidental deaths gave no cause for alarm, thus differing from the American authorities. Accidental death is due either to carbon monoxide in the unburnt gas, or else to the ordinary products of combustion or to carbon monoxide produced by incomplete combustion. To the latter group belong the deaths caused by geysers fixed without flues; to the former group belong the great majority of the deaths—e.g., those due to leaky pipes, absence of stop-pins in burners, disconnexion or defect in flexible tubing and other fittings, and the extinction of a burner by the boiling over of a kettle or saucepan. Like the American Committee, the British Committee discuss the importance of improving fittings and of instituting free periodic inspection, but point out that in many cases the defective fitting is one openly disapproved of by the gas company—e.g., the sliding gas chandelier which has caused 14 deaths during the last eight years. Often the owner persists in retaining a fitting of this sort against the advice of the company. The Committee feel that the many safety devices on the market are not adequately known to the public. The leakage of gas under a road surface is another danger to which attention has been drawn in recent years. The gas industry maintain that this risk is very appreciably reduced by modern methods of road construction and modern methods of laying mains. The Committee discuss the various suggested ways of dealing with the problem, but were unable to find any satisfactory solution. Steel mains would be less resistant to corrosion than cast iron. The production of gas containing a limited proportion of carbon monoxide is being made the subject of experiment both here and in Germany at the present time, and it seems probable that the monoxide could be removed from the gas without substantially increasing the cost. The Committee do not consider, however, that this measure is practicable at the present time, and think that the advantages of cheap gas outweigh the disadvantages of its carbon monoxide content. They therefore recommend that further experiments on the toxicity of gas as now supplied should be carried out. The Committee also see objections to the introduction of irritants and odours which might make escapes more obvious or discourage the suicide. Any irritant would be troublesome to the normal consumer and workman, and any new odour would confuse aged persons. They consider that the gas at present supplied has a sufficiently characteristic and penetrating smell.

Like the Medico-Legal Society, at their discussion on the subject a few years ago,[2] the Committee conclude that the blame for the great increase in suicides cannot be attributed to the gas supply, but is largely accounted for by a general increase in suicide and by a change in the method used. Sir Maurice Craig and Dr. Ingleby Oddie assured them that people who had made up their minds to kill themselves would do so somehow. The prevention lies rather in the realm of the early treatment of mental disorder than in the limitation of an invaluable domestic commodity. Every witness before the Committee agreed with Dr. Douglas Kerr's view, expressed at the discussion mentioned, that the publicity given in the newspapers has suggested gas to many people as an easy way out of life. This however applied equally, they thought, to other methods of committing suicide, even such an agonising one as drinking lysol. The general conclusion of the Committee is that there is no cause for alarm and that they are “unable to suggest any effective measures relating to the production and use of gas, whereby the tendency to commit suicide by gas poisoning may be checked, without imposing on the whole body of gas consumers a financial burden or other inconvenience which is not justified.” They can only recommend the encouragement of research, official records of fatalities, periodic conferences, and an insistence by law on the use of proper apparatus.

PSITTACOSIS IN ARGENTINA.

THE psittacosis epidemic, whose backwash we are now feeling in this country, seems to have been first observed at Cordoba, a town not far from the middle of Argentina, during July and August of last year. Cordoba is a centre for dealers in birds of the parrot tribe, who come there from Brazil and Paraguay, and it has a bird market where auctions take place. About the time mentioned, the doctors of Cordoba were struck by the appearance of numerous cases of a grave character which they diagnosed at first as typhoid, paratyphoid, or malignant influenza. It soon became apparent, however, that the symptoms did not really correspond with the types of any of these diseases, and Dr. Enrique Barros, assistant to the professor of morbid anatomy, discovered that there was coincidently a violent epidemic amongst the imported birds. This gave him the clue to the real diagnosis, and he has now given an account[3] of subsequent investigations into what is probably the biggest outbreak of this epizoötic disease as yet known to us. His meaning is not quite clear, but he says that there were “about 60 certain cases with more than a dozen familial or domestic epidemics and about another dozen of deaths. How many undiscovered cases and of indirect ætiological relation will there be?” Since he himself enumerates 64 it will probably be safe to assume that there were at least 100 cases with not less than 12 deaths. As the bird-dealers became unpopular in Cordoba they transferred their activities to Tucumen, the capital of North Argentina, where an epidemic started in September; but no figures of this are given. There was also an outbreak at Alta Gracia, about 31 kilometres from Cordoba, and at one or two other places along the railway line, following the arrival of the traders. There was also a small epidemic in Buenos Aires, which Barros hesitates to connect directly with those in the interior.

Clinically he describes the disease as presenting symptoms half influenzal and half typhoidal, but with distinctive characteristics. The incubation period is from 7 to 10 days, with a slow onset; the early symptoms are headache, lassitude, and fever which rises rapidly, accompanied at times by rigors and vomiting. Occasionally sore-throat of a diphtheritic type was observed. After the onset this clinical picture gets rapidly worse; there is continuous high fever with slight morning remissions, profound weakness, insomnia, usually delirium, and sometimes excitement, intense thirst, and complete anorexia. The skin is dry and the tongue is furred with red edges; constipation is common. The pulse is rapid (110), soft, and sometimes dicrotic. In some cases there is meteorism, but Barros did not see any splenic enlargement. The most constant and prominent symptoms are pulmonary; every form of pneumonia may occur from the scattered broncho-pneumonic type to massive consolidation. Very characteristic is a constant spasmodic cough without expectoration. Termination, if not by death, is by lysis followed by prolonged convalescence. There is nothing characteristic, says Barros, in the morbid anatomy. He is inclined to think that the bacillus discovered by Nocard in Paris in 1891, which he places in the salmonella group, is the cause of infection, but as he quotes the results of the investigation of but a single case, not much importance can be attached to his conclusions, which are admittedly tentative. His theory is that this organism is habitually present in the intestines of birds of the parrot tribe, and that it becomes virulent under conditions which lower resistance, thus producing the avian epidemic. Such epidemics do not arise in the habitat of the birds, but only when they are brought in large numbers into new and unfavourable conditions. The outbreak at Cordoba he attributes to cold and overcrowding. Once started, the contagion rapidly gets diffused and soon spreads to men—first to the bird-dealers and frequenters of the sale-rooms and then to purchasers. It is interesting to note that in Cordoba the cases were much rarer in women who do not attend sales. Barros does not consider the transference of the disease from man to man as proven. His account of the Cordoba outbreak seems to get us nearer to the actual origin of the disease than anything previously recorded, and the student of epidemiology would be grateful for all the evidence available about the first onset of the disease in birds and men respectively, and the conditions under which it seemed to develop —whether on the journey from the tropical forests or in the town. It is not unlikely, as he suggests, that the transfer of parrots in mid-winter to a cold inland plain entails great suffering for them and is favourable to the disease.

[2] THE LANCET, 1926, ii., 1219.

[3] Rev. Asoc. Méd. Argent., Jan.–Feb., 1930.

On p. 442 Sir Thomas Horder and Dr. Gow give an account of nine cases of psittacosis, with a description of post-mortem findings in two. The four previous issues of THE LANCET have contained original communications or editorial articles on clinical and bacteriological aspects of the infection.

BARBITURIC ACID COMPOUNDS IN ANÆSTHETIC WORK.

SURGEONS who work largely with local anæsthetics are always on the look-out for improved measures by which the patient may be kept in a calm frame of mind although conscious during operation. On the continent, where this method is much more usual than here, many substances have been tried for the purpose, and among them somnifen, which is a mixture of diethyl and dipropenyl barbituric acids, has had a considerable vogue. G. DeTakats,[1] of Chicago, who is well known for his work with local anæsthetics, has lately given an account of valuable experiments which he undertook with somnifen, using the drug both intravenously and into the skin, as well as orally. He regards his attempts to produce a state of somnolence or light sleep by hypnotics of the barbituric acid series as unsuccessful. He finds the results too uncertain, and there is, of course, the objection, common to all injection methods of anæsthesia, that there is no means of recovering or lessening the dose should this prove excessive. DeTakats confirms the opinion previously expressed by others that the barbituric compounds have a protective action against poisoning with cocaine and its derivatives. In contrast with his views may be placed the experience of G. Link,[2] who has used sodium isoamyl-ethyl barbiturate in goitre surgery, and has been so pleased with the results that the drug has been given a routine place in his work. He gives morphia and atropine one hour before operation, and immediately before it an intravenous injection of grs. 5 to 20 of the barbituric acid salt in aqueous solution. The patient falls asleep during this injection, which is made slowly. Nitrous oxide and oxygen are used subsequently during operation. His experience is based on 460 cases. Vomiting after operation is slight, and the condition during operation is described as highly satisfactory, with quiet breathing and good colour, because a large amount of oxygen is admissible.

THE OSLO TUBERCULOSIS CONGRESS.

THE seventh conference of the Union Internationale contre la Tuberculose is to be held at Oslo from August 12th to 15th, under the patronage of the King and Queen of Norway. The sixth conference took place at Rome in September, 1928, when an organisation committee was appointed which has drawn up an attractive programme to include a discussion on vaccination by B C G, to be introduced by Prof. A. Calmette (Paris), one on thoracoplasty in the treatment of pulmonary disease by Prof. P. Bull (Oslo), and one on the instruction of students and practitioners in tuberculosis by Prof. W. His (Berlin). Prof. Th. Frölich, President of the Norwegian National Association, will preside at the discussions which, according to a resolution made in 1924, will be conducted in the French and English languages. Entries should be addressed to Mr. N. Heitmann, secretary-general of the organisation committee, at Cort Adelers Gate 6, Oslo, Norway, or to Dr. F. Humbert, secretary of the Union Internationale, at Avenue Velasquez 2, Paris. In connexion with the conference arrangements have been made for a series of tours and excursions embracing all the attractive features of Norway by road, rail, or steamship, half fares having been granted by the State Railways and some other touring organisations. Inquiries about official tours should be addressed to the Secretary of the Norwegian State Railways, Travel Bureau, Oslo, Norway.

HEALTH INSURANCE AND REJUVENATION.

A GERMAN who, on medical advice, had undergone a rejuvenation operation has attempted to recover the cost of it from his insurance company. The terms of his contract of insurance are not reported, but it would appear that he was insured against ill-health, not against death. He was 60 years old, and his argument was that old age manifested itself in ill-health, that the insurance company would have to pay him for those manifestations, and that therefore it was worth the company's while to bear the much lighter cost of removing the root of the evil; it was, moreover, to the public advantage that his working life should be prolonged. The insurance company replied that old age was inevitable and he was not insured against old age; symptoms of old age, said the company, were distinguishable from symptoms of illness; medical advice was not sufficient justification for the operation; he might please himself about undergoing such an operation on medical advice, but the operation ought not to be at the company's expense. The court of first instance took the company's side on the ground that the manifestations of old age were one thing and incurable sickness another. The Berlin Appeal Court has adjourned the appeal, pending the calling of expert evidence of adequate authority on the medical aspect of the case. Presumably the experts will be asked how far the rejuvenation treatment

[2] Anæsthesia and Analgesia, Jan.–Feb., 1930.

(which the plaintiff said had been successful) can be relied upon to furnish immunities.

Prevention is better than cure, but the insurance companies do not pay for prophylaxis without special agreement. The issue of a fire insurance policy is not accompanied by a free gift of the latest patent fire extinguisher; burglary policies are granted without an undertaking to bear the cost of making the premises burglar-proof. In life insurance a beginning has been made by offering free the benefit of periodical medical examination, but the companies base their business upon the known statistics of life and health and can take no account of prophylactic treatment unless the materials for actuarial estimates are available. There is annuity business, too, to consider. If and when the elixir vitæ is discovered, the companies will have to stipulate that the annuitant shall not take a mean advantage of them.

ADVISORY COMMITTEE ON INDUSTRIAL PULMONARY DISEASE.

THE Medical Research Council announce the appointment of a committee to advise upon the further investigation of pulmonary silicosis and of other pulmonary conditions associated with the inhalation of dusts arising from industrial processes. The members of this committee are :—

Arthur J. Hall, M.D., F.R.C.P., Professor of Medicine in the University of Sheffield and Senior Physician to the Sheffield Royal Hospital (Chairman).

A. E. Barclay, M.D., Lecturer in Radiology in the University of Cambridge.

J. C. Bridge, F.R.C.S.Edin., H.M. Senior Medical Inspector of Factories, Home Office.

S. Lyle Cummins, M.D., Professor of Tuberculosis in the University College of South Wales and Director of Research to the Welsh National Memorial Association.

E. H. Kettle, M.D., M.R.C.P., Professor of Pathology, St. Bartholomew's Hospital and College, London.

E. L. Middleton, M.D., H.M. Medical Inspector of Factories, Home Office (Secretary).

M. J. Stewart, M.B., F.R.C.P., Professor of Pathology in the University of Leeds.

Cecil Wall, D.M., F.R.C.P., Physician to the London Hospital and to the Brompton Hospital for Consumption and Diseases of the Chest.

This advisory committee will survey the present state of knowledge, will advise the Council upon new lines of inquiry that may be profitably pursued, and will assist in the supervision of such investigations as it may be decided to initiate or support. The work will be directed particularly towards obtaining, in coöperation with the Factory Department of the Home Office, more accurate knowledge of the causes and diagnosis of silicosis and of other industrial pulmonary disorders. The need for better knowledge of these subjects has been emphasised by the recent Report of the Silicosis (Medical Arrangements) Committee, whose recommendations to the Secretary of State for extended research work have been referred to the Council by the Home Office.

DOUBLE-SHIFT SCHOOLROOMS.

Mr. David L. Tweedie, member of a firm of Dundee solicitors, tells us that he has solved the problem of school accommodation by devising a time-table with two shifts, analogous to the late Lord Leverhulme's proposal for the full utilisation of industrial plant. Pupils from 5 to 12 years of age would attend for five 50-minute periods from 9 A.M. to 2.50 P.M., those 13 to 18 years of age for five similar periods from 3 P.M. to 8.40 P.M. Such an arrangement would allow for the extension of school age to 18 years without any addition to the number of schools, and without interfering with the meal hours of pupils or affecting their health. It would, Mr. Tweedie suggests, ensure time for home preparation of school subjects, and would finally remove the need for Parliament or any educational authority to do more than find the income to meet the additional annual outlay. Mr. Tweedie's idea is attractive and ingenious but it is not altogether new; in New York, for instance, such a scheme of school shifts is in working. It is conceivable that some similar arrangement might be tried to tide over temporary difficulties in this country; but Mr. Tweedie seems to ignore the question of staffing which would be an almost insuperable bar to his scheme from the educational side; while, from a health point of view, the double shift would make such schools and buildings as are at present unsuitable and insanitary still more offensive. Curricula are already overcrowded and intensive methods are apt to defeat their own ends with growing children and react badly on their health, at all events on this side of the Atlantic. Increased homework would give unequal results, for conscientious children flag under it, whereas the others are protected by natural indolence. It is doubtful, too, whether the available plant is there. Certainly in London, where a great number of schools are used for night classes, there is trouble now in finding suitable desks, seats, and furnishings for adolescents and adults, and the problem of lighting is serious. We do not think Mr. Tweedie has done more than state a case.

DIRECT VERSUS INDIRECT LIGHTING.

A RECENT Home Office pamphlet[1] gives a useful summary of the relative advantages and disadvantages from the industrial point of view of alternative methods of artificial lighting. One of the main essentials to a good system is the prevention of glare. This term is used to cover either one of the following phenomena: (1) the temporary dazzle caused by looking directly at a bright source of light such as an arc lamp, so that the worker is for the time being prevented from seeing other objects properly; (2) the effect produced by the presence of one or more bright sources of light towards the edge of the field of vision so that the rays enter the eye obliquely from them—this is prejudicial to the vision of objects in the more central part of the field even though the rays from the sources of bright light may never fall on the macular region; (3) the effect which is produced when the surface of cloth, metal, paper, or other material being worked upon is shiny or polished and reflects light directly into the eyes of the worker. The reflection of light from the glass of a glazed picture is a familiar example of the same thing. The first two forms of glare can be avoided either by the proper shading of the source of light or by fixing them at a sufficient height above the worker. The third, which is liable to be troublesome when the working material is polished, may be remedied either by the suitable adjustment of the source of light in relation to the eyes of the worker, or by employing diffused light—i.e., light reflected from a large surface such as a ceiling or wall. This indirect method of lighting has the further advantage of reducing to a minimum the shadows which are specially prejudicial to certain kinds of work—e.g., that of the compositor. On the other hand, indirect lighting is less economical than direct. In some instances it may even be that the production of shadows is an advantage. The perception of detail in certain classes of material depends on the contrast produced by miniature shadows on the surface—e.g., a uniformly coloured card with embossed design, or a self-coloured textile material in which miniature furrows lie in shadows cast by miniature ridges. On such material it was found that for comfortable working a higher illumination was required with indirect than with direct lighting. For the combination of efficiency with economy the pamphlet emphasises the importance of fitting the method of illumination to the particular purpose which it is meant to serve. For some sorts of work direct lighting under suitable precautions may be recommended, for others indirect lighting.

AN ESSAY IN SEX DETERMINATION.

Prof. F. Unterberger, Director of the Gynæcological Section at the Königsberg Hospital of Mercy, has published in the current number of the *Deutsche medizinische Wochenschrift* (Feb. 21st, p. 304) an interesting account of a suggestive excursion into sex determination. He has found that the sprinkling of a little powdered sodium bicarbonate on the glans penis before cohabitation will vastly increase the probability of the resulting conception being a male. He was led to begin his investigation when he learned that sterile cows often became fertile after alkaline vaginal douching, and he discovered that the acidity of the vaginal secretion was unduly high in women who came to him complaining of sterility. An alkaline vaginal douche often led to conception in these women, and to his amazement always conception of a boy. Having the practitioner's dislike for vaginal douches, he then began to recommend the introduction of the sodium bicarbonate in the way indicated, whose utmost drawback has been a slight tickling sensation in consequence of the carbon dioxide evolved. The result, in a series of 53 cases in which there was a complaint either of sterility or persistent girl-bearing, was *always* a boy. In every case the vaginal acidity was high before the test. He made some attempt to check the results by animal experiment but found the technical difficulties very hard to surmount. The method is, indeed, so simple and harmless as to be tried almost without compunction on the human subject, and the Königsberg claim will no doubt lead to carefully controlled observations in this country. The success of the method would have some bearing on the mechanism of sex determination. Prof. Unterberger is himself an adherent of the view that the ripe egg-cell is indifferent, the sex of the conception being determined by its impregnation with one or other of the two types of spermatozoon containing respectively 24 and 23 chromosomes. It does not, therefore, surprise him that the exertion of some chemical influence on the spermatozoa might lead to the preponderance of the effect of one or other of these types of spermatozoon.

THE FELLOWSHIP OF THE ROYAL SOCIETY.

The fifteen candidates for Fellowship of the Royal Society recommended by the Council for election this year include the names of two medical men, Prof. W. W. C. Topley and Dr. Charles Todd, and several others whose work closely touches medicine. Prof. Topley has not only made notable contributions to pure bacteriology, but has devised and pursued methods of studying artificially produced epizoötics in experimental animals which have already advanced our knowledge of immunity, and have shown how complex are the problems involved in the study of epidemiology. Dr. Todd is attached to the Department of Experimental Pathology, Bacteriology, and Protistology of the National Institute for Medical Research, Hampstead, where he is continuing his serological work, started in Egypt, on the specificity of the hæmolytic power of blood-serums in connexion with heredity. Among the proposed Fellows whose research is directly associated with medical problems are Mr. H. W. Dudley, Ph.D., who is on the staff of the department of Biochemistry and Pharmacology at the National Institute for Medical Research, and Mr. R. Robison, who works as a biochemist at the Lister Institute. They are well known to our readers. Dr. Dudley has studied especially histamine and other chemical factors of vascular control, and it is to Mr. Robison that we owe the discovery that bone and ossifying cartilage contain an enzyme, phosphatase, which is regarded as an active agent in ossification. Lieut.-Colonel John Stephenson (I.M.S., ret.) was, from 1920 to 1929, lecturer in zoology in the University of Edinburgh. He is an authority on the fauna of British India. Mr. E. K. Rideal (son of Mr. Samuel Rideal, D.Sc.) is Owen Jones Lecturer in Physical Chemistry in the University of Cambridge, Mr. F. T. Brooks is a plant pathologist, and Mr. H. Eltringham an entomologist. The other names put forward are Mr. E. B. Bailey, of His Majesty's Geological Survey Department, Mr. A. M. Dirac, Ph. D., a mathematical physicist, Mr. C. A. Edwards, D.Sc., Professor of Metallurgy, in the University of Wales, Mr. H. S. Allen, D.Sc., Professor of Natural Philosophy in the University of St. Andrews, who has made a special study of the interpretation of the quantum, Mr. C. Inglis, Professor of Mechanism and Applied Mechanics in the University of Cambridge, Mr. Harold Jones, D.Sc., H.M. Astronomer at the Cape of Good Hope; and Mr. G. P. Thomson (son of Sir J. J. Thomson) who is Professor of Natural Philosophy in the University of Aberdeen.

FOOD OR DRUG?

Many preparations now put on the market by manufacturing chemists owe their virtue to the inclusion of food constituents such as vitamins. Social reformers and other altruists are wont to advocate the use of these preparations on a large scale for the insured population by including them in the schedule of drugs which chemists undertake to supply for their treatment. The drug fund, however, was never intended to provide food or to make good deficiencies in the diet of the worker and his family. The Insurance Act provides that "proper and sufficient medicines for the adequate treatment" of the insured patient shall be supplied at the cost of the fund; and it has not proved easy in practice to interpret this seemingly straightforward direction because although a number of preparations are certainly never drugs and others are certainly always drugs, there are a number which are drugs in some circumstances and not in others. The insurance practitioner can, however, now fall back upon the tables (reprinted on another page) drawn up by the advisory committee over which Dr. D. G. Greenfield presided. The report of what may conveniently be called the Greenfield Committee will enable the practitioner to distinguish more clearly between a drug and a food and to place certain substances about which doubt has arisen in their proper category, and it will guide panel and insurance committees in their administration of medical benefit in such a case as came recently before the London Insurance Committee when, after an inquiry by the Ministry of Health, a firm of four practitioners were penalised to the extent of £100 for lavish prescribing of such things as malt and cod-liver oil in a neighbourhood where conditions of life were hard and nutrition was bad. The referees held that the wholesale administration of cod-liver oil in insurance practice was only legitimate as an experiment, conducted under experimental conditions. It was impossible to countenance idealism at the expense of a limited public fund. In the *Saturday Review* of Feb. 15th Dr. F. G. Layton sharply criticises the principles of medical benefit thus laid down, but he omits to point out that the four doctors in question have had all the consideration which the Insurance Acts allow. Their case was examined first by a professional committee of their colleagues and then by the insurance committee with a final appeal to three independent referees. This board of referees is composed of two medical practitioners and one lawyer, in actual practice. Each time they had the opportunity of stating their position and of being represented before the referees. From the information before us it would appear that they exceeded what was considered by their compeers as reasonably necessary for the adequate treatment of their patients; they ordered on an average nearly seven prescriptions for each patient on their list, whereas the average for the kingdom is less than four; in certain cases the same drug was ordered in two forms for the same patient on the one prescription paper; and they prescribed cod-liver oil for its nutritive value, whereas it has always been held that nothing in the nature of food should be ordered at the expense of a fund intended only to provide drugs. Such prescribing is at the expense not merely of the drug fund but of neighbouring practitioners. Those who administer the Acts are agreed that insured persons should get as good treatment as do private patients, but it is doubtful whether any class of private patient could afford to pay for treatment on the scale mentioned.

THE OVARY-STIMULATING HORMONE.

FOLLOWING the report, noted in these columns a short time ago (THE LANCET, Jan. 11th, p. 94), of the isolation by E. A. Doisy and A. Butenandt independently of the œstrus-producing hormone of the ovary in a crystalline form, considerable interest has been aroused by the recent announcement in the lay press of a discovery by Dr. J. B. Collip, whose development of Banting and Best's process for obtaining insulin from the pancreas has played an important part in the therapeutic use of this substance. A preliminary paper by Dr. Collip on the Ovary-stimulating Hormone of the Placenta appears in the February issue of the *Canadian Medical Association Journal*, which has just reached us. Dr. Collip points out that abundant proof exists that the placenta contains the œstrus-producing hormone known as œstrin. Since the original work of Allen and Doisy on follicular fluid as a source of this hormone, œstrin has been demonstrated in the placenta, in the amniotic fluid, and in the urine of pregnancy. Here it is associated, as has been shown independently by Smith and Engle, and by Zondek and Aschheim, with another water-soluble hormone having properties quite distinct from œstrin. This other hormone has been thought to be derived from the anterior pituitary body, since intramuscular injection of extracts of this gland produce the same effects, that is, a rapid development of the immature ovary in the rat or mouse. The connexion between these hormones is of the utmost interest, for as a result of the stimulation of ovarian activity by extracts from anterior pituitary hormone œstrin is liberated, producing its typical effects (a hypertrophy of the genital tract and the phenomena of œstrus). Both hormones cause the same ultimate effect, but Dr. Collip points out the clear distinction between them. The anterior pituitary hormone acts indirectly by stimulating the ovary to produce œstrin, and therefore is ineffective in castrated animals; whereas œstrin acts just as effectively in a castrated female as in a normal one. This distinction, which arises from the work of Engle and Smith and Allen and Doisy, has been amply confirmed by other workers. Dr. B. P. Wiesner and Mr. J. S. Patel,[1] of the Department of Animal Breeding in the University of Edinburgh, have gone a step further. They have succeeded in preparing potent aqueous extracts of the ovary-stimulating hormone from human placentæ by extraction with sulphosalicylic acid. Dr. Wiesner visited Dr. Collip's laboratory at the McGill University in September last and "demonstrated in a single but convincing experiment the effectiveness of the sulphosalicylic acid extract of fresh human placenta in producing premature maturity in the young rat." At Wiesner's request, Dr. Collip made attempts at the concentration of the premature maturity-producing principle in the placental extract, the presence of which he has confirmed by many experiments. It soon became apparent, however, that the sulphosalicylic acid in the extract presented a formidable barrier to further concentration and purification of the active principle. Various methods of extraction and fractionation were therefore tried and the active principle has now been obtained, free from protein, salt, lipoid, and œstrin, in the form of an aqueous solution which may be administered either subcutaneously or orally. It is possible, says Dr. Collip, to place the equivalent of 100 g. of placenta in 1 c.cm. of water with a relatively small loss of the active principle contained in the original tissue. The potency of the extract can be standardised by a modification of the method of Zondek and Aschheim. In order to ensure that it is free from œstrin it must be without effect on castrated animals. Whether, as has been assumed by some workers, the ovary-stimulating hormones derived from different sources are all the same and are all derived from the anterior pituitary gland is not proven. The hormone *may* be secreted by the pituitary gland and stored in the placenta, but Dr. Collip inclines to the belief that it is actually elaborated in the placenta. This contention is supported by the fact that the placental hormone, unlike the anterior pituitary hormone, is effective by the mouth, and it appears to have other properties distinguishing its action from that of extracts of the anterior pituitary gland. The point is at present mainly of theoretical interest. The concentration and purification from the placenta of the active principle by means of fractionation processes (to be described later) have been brought by Dr. Collip to a point where one rat unit may be represented by 0·01 mg. of dry substance. Certain micro-crystalline fractions of great potency have been obtained, but it is impossible to state as yet whether such fractions are pure chemicals. The dosage by mouth may be not more than two or three times the effective subcutaneous dose. Injection of the active extract into adult castrates is without effect. The laboratory results reported in Dr. Collip's preliminary communication are based on assay studies of 150 immature rats, and have seemed to justify experimental clinical study. In the same issue of the *Canadian Medical Association Journal* Dr. A. D. Campbell and Dr. Collip publish a preliminary report on the clinical use of the substance. "Definite results of a most encouraging character" have already been obtained in five cases of scanty menstruation, in two cases manifesting distressing menopausal symptoms, and in two cases of dysmenorrhœa. It is hoped with good grounds that further studies may throw new light, not only on problems of ovarian dysfunction and hyperthyroidism, but also on some of the toxæmias of pregnancy.

RECONSTRUCTION OF SUNDERLAND INFIRMARY.—The reconstruction of this hospital is about to be advanced a step farther by the provision of a new administration block at a cost of £36,000. The present block is totally inadequate, and its replacement has become urgent; it will be demolished when the new building is ready. The work forms part of a comprehensive scheme estimated to cost £150,000, which began with the construction of the Princess Mary wing of 95 beds. A similar block has yet to be erected, but meanwhile there has been an addition to the plan in the shape of a pathological department, now under construction.

LONDON IRISH MEDICAL GOLFING SOCIETY.—A successful dinner and dance was held at the May Fair Hotel on Feb. 20th, Mr. Hugh Lett presiding. Over 300 members and guests were present, amongst the latter being Mr. Arthur Greenwood, M.P., Mr. V. Alexander, M.P., and Sir Robert Stanton Woods. The speakers included Lord Russell of Killowen, Lord Moynihan, Mr. Hugh Lett, and Mr. M. J. Smyth. The menu was skilfully devised to suit the occasion, containing such items as pommes au roi d'argent and salade greensome, and the company showed every sign of enjoying the fare provided.

THE END OF A FLOATING HOSPITAL.—Some 35 years ago a floating hospital was erected at Jarrow for the detection and treatment of foreign-borne diseases, and during the war patients from all vessels of the navy entering the Tyne were treated there. During the last 10 years the hospital has been little used, and since repairs would be costly the Ministry of Health and the Tyne Port Sanitary Authority have agreed that it shall be sold and broken up. In future patients who would have been received within it will be sent to the Walker Gate Hospital.

MR. C. BOWDLER HENRY: INTERPRETATION OF DENTAL RADIOGRAMS.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

LXIV.—THE INTERPRETATION OF DENTAL RADIOGRAMS.

PART I.*

General Observations.

AT the outset it should be appreciated that a radiogram is but one link only in the diagnostic chain, and though it be a very important one, its value is directly proportional to its proper usage as one component of a whole. To condemn or to exonerate questionable teeth upon their radiographic appearances alone is to do so upon insufficient, and sometimes faulty, evidence.

When it is at all feasible, radiographic findings should be correlated with the results of a clinical dental examination. Dental surgeons and their patients sometimes suffer when a doctor, after a cursory inspection of dental films, expresses an opinion, often founded on an incorrect interpretation, contrary to the considered advice of the dentist. It is highly desirable, therefore, that the doctor should be versed in the interpretation of dental radiograms, so that he can correlate them with the clinical reports and decide on appropriate action. Though dental sepsis may not be sufficiently potent in a particular case to cause a secondary lesion, it is capable, even in mild degrees, of swinging the balance, and it may also put an effective drag on recuperation. Dental radiograms should therefore be taken in all cases of debility or chronic ill-health.

The practice of radiographing suspicious teeth and ignoring edentulous spaces is unwise; to take the patient's word that he is edentulous is often to miss a hidden source of focal infection. At the Mayo Foundation all patients are submitted to a dental examination, which includes a full set of films, as a matter of routine.

Examination of Dental Films.

It is not sufficient to hold dental films casually to the light and note only the gross changes, such as impacted teeth, the outline of cysts, or the presence of obvious apical rarefaction. The films should be examined first generally by the naked eye and then critically with a lens over a suitably diffused source of light, such as an opal glass electric lamp

---

* Part II. will appear next week.

DESCRIPTIONS OF ILLUSTRATIONS ON SPECIAL PLATE.

MR. C. BOWDLER HENRY: INTERPRETATION OF DENTAL RADIOGRAMS.

The illustrations show one-half of a fairly normal set of dental films, some examples of errors of interpretation which may arise through taking radiograms from an incorrect angle, and some teeth with caries and periodontal disease. Some of the teeth have had fillings, shown as radiopaque (white) clearly defined areas.

FIG. I.—(A) Malar process often casts a radiopaque shadow (Z) over the apices of the upper molars.

(B) The antrum, delineated by an even line (Y), is in close proximity to the premolar and molar roots. In order to display the antrum this film was taken from an angle which makes the premolars appear foreshortened.

(C) Shows the first premolar, canine, and lateral incisor, from left to right of film.

(D) Shows anterior palatine fossa (W) in correct position between the apices of the central incisors. The nasal fossæ are in close relation to the apices of the central incisors.

(E) Shows same fossa (W) superimposed upon the apex of the right central incisor, and might be mistaken for area of rarefaction. This film, of which the left half only is reproduced, was taken to show the lateral incisor. The angulation, therefore, was incorrect for the central incisors. This shows the need for taking enough exposures to obtain correct angulation.

(F) Inferior dental canal (V) shown below apices of molar teeth.

(G) Mental foramen shown as a dark patch (U) between and below apices of first and second premolars.

(H) Lower incisors.

FIG. II.—Foreshortening of the image of the upper central incisors (the same teeth as shown in Fig. I., D) due to using too high an angle. Foreshortening and absorption with regeneration of bone are easily confused, and confirmatory radiograms are desirable in all cases where foreshortening occurs.

FIG. III., C.—Photomicrograph of the amelo-gingival junction in a young dog. Nasmyth's membrane can be seen sagging towards the tooth, the subjacent enamel having been dissolved away. The epithelial barrier formed by the junction of the membrane and epithelium of the gingival trough is the first defence to be broken by the ingress of pyorrhœa. A = Space created by the solution of the enamel. N = Nasmyth's membrane (enamel cuticle); the membrane collapsed towards the dentine on account of loss of support when the enamel was dissolved. G.C. = Gingival crest. C.E. = Crevicular epithelium. D. = Dentine.

FIG. IV.—Upper and lower third molars (T) in a boy aged 17. Owing to lack of developments antero-posteriorly in the jaws these molars are unable to erupt into normal position. The inclination of each presents the commonest variation. The lower is locked with the second molar and has prevented it from erupting normally. This boy's only sister (older), his mother, and his mother's brother had similarly impacted third molars.

FIG. V.—The mental foramen (S) is subject to variation of position and may appear in close apposition to the apex of the second premolar simulating a pathological area of rarefaction.

The first premolar in this film exhibits an advanced stage of local periodontal disease aggravated by traumatic occlusion with the teeth of the opposing jaw. Note the loss of alveolus and the open funnel-shaped socket produced by the marginal rarefaction.

FIG. VI.—Caries (R) in distal aspect of second molar shown as a black patch. Ragged edge (P) to faulty filling has encouraged food stagnation with production of a deep pyorrhœa pocket (Q). Advanced periodontal disease between molars in a patient of good resistance, who has put up a sclerotic barrier in the cancellous tissue of the septum (O).

FIG. VII.—Caries (R) below a filling shown as a dark radiolucent halo. Death and putrefaction of the pulp has led to chronic apical infection (N).

FIG. VIII., A.—Shows evil following extraction of first permanent molar, viz.:—

(1) Occlusion with the opposing upper molars is thrown out of gear. Therefore loss of natural function and cleansing.

(2) Food impaction between the molars has produced caries (R) and an incipient pocket.

(3) Food stagnation under the tilting side of the crown has produced a deep pyorrhœa pocket (M). Ultimately the tooth will be lost.

FIG. VIII., B.—Periodontal disease produced or aggravated by subgingival tartar (L) seen as projections on the side of the roots with well-defined pockets below.

SIR THOMAS HORDER AND DR. GOW: PSITTACOSIS.

FIG. I. (Case 3).—Part of lower lobe of left lung. The general lung tissue is of a greyish colour due to a somewhat solid form of œdema. There are patches of pneumonic consolidation, chiefly subpleural in distribution, into which hæmorrhage has occurred freely. (Drawing made by Mr. W. Thornton Shiells after specimen had been prepared for Museum.)

FIG. II. (Case 9).—Lower lobe of left lung. At the base the pleura is covered with a fine exudate through which small subserous hæmorrhages are visible. On the cut surface near the middle of the lower border is a firm grey asbestos-like patch of consolidation surrounded by an area of hyperæmia. The lung in the centre of the lobe is œdematous and brownish-grey in colour. Beneath the pleura, to the left, the lung shows a patch of almost confluent consolidation, red in colour. The bronchi show no gross change. (Drawing made by Mr. Shiells immediately after autopsy.)

FIG. III. (Case 3).—Thrombosed vessel with neighbouring area of consolidation, and on the left œdema.

FIG. IV. (Case 3).—An area near a region of necrosis, showing the coagula in the alveoli.

FIG. V. (Case 9).—Consolidated area. Two structures at the periphery, somewhat resembling coagula in Case 3.

FIG. VI. (Case 9).—Margin of a necrosed area.

or preferably a proper viewing box. The films should be the best procurable. Even when the definition of the radiogram is very fine, imagination must play a large part in visualising the morbid anatomy of the parts seen, and therefore mediocre radiograms are misleading. Only the central portions, where the rays have penetrated the tissues and impinged upon the film with correct incidence, should be used, and the outer portion of a film where the image may be distorted should be discounted. A sufficient number of exposures should be made to make this possible. Twelve of the stock size dental films is, in my opinion, the minimum, supplemented when occasion arises by two more and by stereoscopic films of uncertain areas. The doctor should make it his duty to learn, by watching dental films being taken, the relative positions of tube, tissue, and film for the various groups of teeth in the average mouth.

Examples of the importance of taking several views are illustrated in Fig. I., E, where the shadow of the anterior palatine fossa has been transposed behind the apex of the lateral incisor, giving rise to the appearance of an apical rarefaction; and in Fig. II., where by using too acute an angle of incidence the radiologist has produced an appearance of foreshortening which resembles a type of absorption of the roots of the teeth occurring in one manifestation of dental sepsis. The desideratum is that the shadow of a tooth projected on to the film should appear identical in length with the tooth, but, as the dental film cannot be placed in an ideal radiological position, the factors of human judgment and error cannot be entirely eliminated. Some radiologists tend to foreshorten the images of certain teeth, whilst others tend rather to elongate them.

With the films upon a viewing box in a suitably darkened room a general inspection should be made first to note general characteristics not merely of the teeth themselves, but particularly of the periodontal membranes and of the cancellous tissue of the jaws in this region.

FIG. III., A.

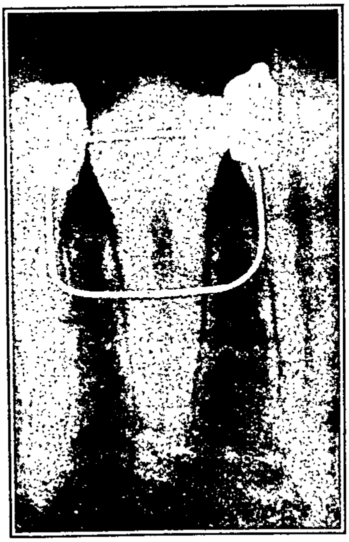

FIG. III., B.

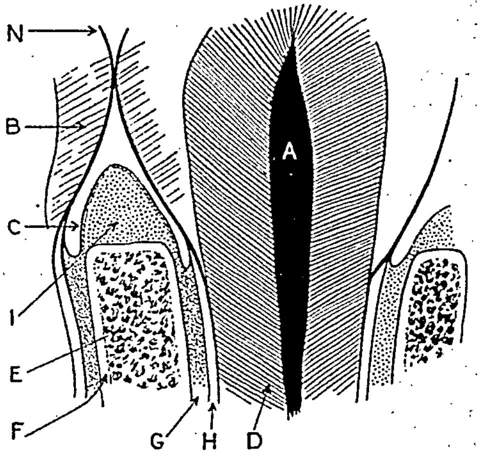

III., A.—Enlarged radiogram of one of the normal premolars shown in Fig. I. A diagram of the framed portion is shown in Fig. III., B.

III., B.—A = Pulp. N = Nasmyth's membrane, epithelial layer covering enamel (B) and reflected on to gum at the termination of the enamel in the gingival trough. C = Gingival trough lined by epithelium (see Fig. III., C). D = Dentine. I = Interdental papilla not visible in X ray, greatly filling space between the teeth. E = Cancellous bone of interdental septum. F = Lamina dura which appears as white line in X ray and is continuous over top of septum to the next socket. G = Periodontal membrane which appears as black line in X ray. It has strong fibrous bands which sling the tooth in the socket. H = Cementum which secures the ends of the fibrous bundles to the dentine.

A General Survey.

In the general preliminary survey the following points should be noted:—

1. The arrangement of the teeth in relation to the normal position (see Fig. I.). In the normal young adult with a well-developed arch the teeth are arranged vertically in perfect order, the crowns of adjacent ones in contact but not overlapping, and the roots on all of them tapering to finely pointed apices. In length the roots are approximately twice the height of the crowns. When the premaxillary region is underdeveloped (due probably to early adenoids), the arch of the teeth is pinched in this region and malposition and overlapping of the incisor teeth in varying degrees result. Underdevelopment posteriorly causes shortening of the jaws in an antero-posterior direction, when the third molars (or wisdom teeth) of both jaws are unable to erupt easily in a vertical direction and may even remain buried. They are subject to considerable variation of position. Fig. IV. shows one of the typical misplacements, the importance of which is discussed below.

2. The presence of other unerupted teeth, supernumerary teeth, and foreign bodies, and the tilt or evidence of undue stress in teeth adjacent to edentulous spaces or supporting artificial dentures.

3. The character of the osseous framework generally and any gross changes in this tissue such as sclerosis or rarefication.

4. The position of those normal structures both radiolucent and radiopaque, which act as landmarks. Normal structures may be mistaken for pathological conditions, or may be encroached upon by morbid conditions occurring around the roots of the teeth.

Structures in the Maxillæ.

The delineation of the *antrum* (Fig. I., B) by a thin layer of hard bone surrounding a radiolucent area above the molar and premolar teeth should be observed. This sinus extends sometimes as far forward as the lateral incisor, and is often mistaken for an area of pathological destruction especially when septa dividing it into loculi are present. Conversely, a small dental cyst invading the antrum may easily be mistaken for a loculus of that sinus. Stereoscopic plates and a comparison of the two sides are helpful in avoiding such errors. A large dental cyst displacing the floor of the antrum upward and filling the entire space formerly occupied by that cavity may also be unrecognised, but with this the physical signs are more apparent.

The *malar process* (Fig. I., A) often casts a radiopaque shadow over the apices of the last upper molar teeth, preventing clear definition. It should not be mistaken for an area of pathological sclerosis.

The tip of the *coronoid process* sometimes appears on an upper molar film.

In the front of the mouth the *median suture*, the *anterior palatine canal, foramen and fossa* (Fig. I., D) may be mistaken for periapical destruction above one or other of the central incisors, especially when the tooth is known to be pulpless.

The *nasal septum* often throws a radiopaque shadow across the roots of the upper incisors, and the *nasal fossæ* are sometimes observed in close relationship to the apical extremities of the central incisors (Fig. I., D).

The *canine fossa* over the lateral incisor and the canine varies greatly in depth, and radiograms of this region show corresponding variation in radiolucence.

Structures in the Mandible.

The *inferior dental canal* is seen extending forward below the roots of the molars and premolars in Fig. I., F. Disease of these teeth is a frequent source of chronic trouble in this branch of the trigeminal nerve, which may persist indefinitely after the teeth themselves have been removed. It will be noticed that the canal is closer to the third molar than the other teeth, a fact which is of importance in surgical procedures connected with this tooth. Impacted third molars are found not uncommonly grooved, where they were in contact with the nerve.

The *mental foramen* (Fig. I., O) is seen as a radiolucent area between the apices of the first and second premolars. Sometimes it is hardly to be distinguished, but at other times it may appear so closely applied to the root of a premolar as to simulate a morbid condition of this tooth and forms a common pitfall in diagnosis (Fig. V.). If the radiogram is of proper texture determination may be greatly aided by tracing the inferior dental canal to the foramen and by radiograms taken from different angles, coupled with the electric test for vitality of the tooth concerned.

In the region of the lower molar roots and roughly parallel to the mandibular canal, but above it, is a radiopaque band. It is a shadow thrown partly by the *mylohyoid line*, which is lingual to the molar roots, and partly by the dense bone of the *external oblique line*, which passes to the outer side. In strongly built subjects this shadow is sufficiently opaque to obscure the detail of the roots of the last two molar teeth.

Having reviewed these anatomical variations before proceeding to the critical examination, it is wise to look at the radiograms as a whole, noting any change common to them all, such as increased or decreased definition of the roots, increased or decreased thickness of the trabeculæ of the cancellous bone, general loss of the alveolar edges, the presence of any unusual degree of apical rarefaction, or of sclerosis.

Detailed Inspection.

After a general inspection radiograms of the teeth should be examined seriatim with a lens, the observer paying attention to the structures described below and shown in Fig. III., A and B.

1. *The crown.*—The enamel is clearly defined as a cap of denser material covering the exposed portion of the tooth, being thickest in the cusps on the masticating surface and thinning to its termination at the neck of the tooth, where it ends in a delicately chamfered edge (Fig. III., A and B) having no projecting ledge or sudden break. Fillings and artificial crowns should be made to imitate this smooth continuity of surface from root to crown as closely as possible, otherwise stagnation of food occurs at this rough place with injury and infection of the subjacent periodontal membrane, and ultimate caries in the root deep to the filling (Fig. VI.).

Caries beneath a filling may be seen as a radiolucent (dark) area extending even down to the pulp, and is a source of neuralgia and later of infection and death of the pulp (Fig. VII.). The position of the crown relative to its neighbours should also be noted. A slight breach at the point of contact, leading to food impaction, or undue tilting of the crown, interfering with proper cleansing, gives rise to caries (Fig. VIII., A) and to periodontal infection. For the same reason the presence of subgingival tartar should not be overlooked (Fig. VIII., B).

2. *The pulp chamber and canals.*—These should have a regular, clear outline. Secondary dentine—as an inward bulge upon the pulp boundary—or pulp nodules may give rise to neuralgia from a tooth externally normal and clinically alive. This deposition of dentine within the pulp and the much rarer destruction of dentine proceeding from the pulp outward are the only affections of the pulp which are portrayed in a radiogram. It is not possible to distinguish whether a pulp is dead or alive. When the pulp has been extirpated and the root filled with radiopaque material, such as gutta-percha, the apparent mechanical success of the operation should be observed; but a well-filled root does not necessarily mean a sterile, healthy root, for the dentinal tubules may be full of septic material. It is one stage better, however, than a poorly filled pulp chamber or than a pulpless tooth with no root filling at all.

3. The *root of the tooth, the periodontal membrane*, and the *lamina dura* of the socket should be examined together. The *surface of the root* should appear smooth and should pursue a regular course toward the apex. There should be no excrescences or excavations upon it and the apex should be moderately pointed, unless bending of the root toward or away from the rays hides it. As the dentine is denser than the bone, the shadow cast by the root obscures that of the superimposed and subjacent cancellous tissue, except occasionally toward the end of finely tapered roots, where the cancellous network may even interfere slightly with the shadow of the root apex. The *periodontal membrane*, interposed between the tooth and the wall of the socket, appears as a fine, black radiolucent) line, clearly defined and of even thickness, except at the apex of the root, and of almost the same tenuity as a hair. The *lamina dura* of the socket is seen as a thin white (radiopaque) line of compact bone covering the cancellous tissue of the alveolar processes. There should be no breach in its continuity.

4. The *crests* of the interdental septa are formed by the junction of the laminæ duræ of the adjacent sockets where they join that covering the cancellous tissue of the septum. Between the incisor teeth, where the interproximal spaces are narrow, the septal crest appears as a thin, elongated spine of hard bone formed by the convergence of the laminæ duræ of the two socket walls (Fig. I., C). Toward the back of the mouth, owing to the greater convexity of the crowns of the teeth, the interproximal spaces become broader, and here the lamina dura passes straight across from the margin of one socket to that of the next (Fig. I., G).

5. The *cancellous tissue* of the bone between and around the teeth. Its recognition is largely a consideration of the thickness of the trabeculæ, the spaces which they enclose, and their general arrangement. In the maxillæ the pattern is that of a fine, irregular small meshed honeycomb; while in the mandible the trabeculæ form large irregular spaces with a general tendency downward and forward in the premolar and molar region.[1] No definition, however, of normal appearing cancellous tissue can be given and in apparent health it is subject to considerable variation.

C. BOWDLER HENRY, M.R.C.S., L.D.S. Eng.,
Assistant Dental Surgeon, Royal Dental
Hospital of London.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 15TH, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 322 (last week 374); scarlet fever, 2680; diphtheria, 1896; enteric fever, 41; pneumonia, 1330; puerperal fever, 45; puerperal pyrexia, 118; cerebro-spinal fever, 13; acute poliomyelitis, 13; encephalitis lethargica, 15; dysentery, 6; ophthalmia neonatorum, 111. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Feb. 18th-19th was as follows:—Small-pox, 563 under treatment, 30 under observation (last week 571 and 26 respectively); scarlet fever, 2247; diphtheria, 2821; enteric fever, 17; measles, 1048; whooping-cough, 93; puerperal fever, 29 (plus 17 babies); encephalitis lethargica, 121; "other diseases," 14. At St. Margaret's Hospital there were 13 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox (assigned to Enfield U.D.), none from enteric fever, 79 (29) from measles, 12 (4) from scarlet fever, 31 (2) from whooping-cough, 55 (17) from diphtheria, 38 (15) from diarrhœa and enteritis under two years, and 80 (14) from influenza. The figures in parentheses are those for London itself.

Fatal cases of measles were concentrated at Portsmouth 13, Manchester 12, West Ham 5. Deaths from whooping-cough at Liverpool 7, Bradford 4. Diphtheria claimed 6 victims at Liverpool, 4 at Birmingham, and 3 each at Tottenham and Salford. Eight deaths from influenza were reported from Birmingham, 5 from Liverpool, 4 each from Salford, South Shields, and Newcastle-on-Tyne.

---

[1] Colyer, J. F., Dental Surgery and Pathology, fifth edition, 1923, chap. xxxvii.

The number of stillbirths notified during the week was 263 (corresponding to a rate of 39 per 1000 births), including 54 in London.

Fatal Case of Small-pox.

The fatal case of small-pox which occurred in the urban district of Enfield, was that of an unvaccinated male, aged 70 years, taken ill on Jan. 27th, when the rash first appeared. There was no preliminary complaint of any kind, and the rash was profuse, pustular, and confluent. Dr. D. H. Geffen, medical officer of health, was called in on Jan. 30th, when a diagnosis of small-pox was made. The patient died on Feb. 6th.

Special Articles.

OPENING OF THE CENTRAL CLINIC FOR TREATMENT OF RHEUMATISM,

PETO-PLACE, MARYLEBONE.

ON Tuesday last the new central clinic for the treatment of rheumatism, built and equipped by the British Red Cross Society at Peto-place, Marylebone-road, London, N.W. 1, was opened by H.M. the Queen. The prevalence of rheumatic diseases in this country is so great that the Ministry of Health attributes nearly one-sixth of industrial invalidity to them. These cases cost nearly £2,000,000 yearly in sick benefit, and over 3,000,000 weeks of lost work. During the last four or five years the approved societies and the medical profession together, realising the waste of time and money caused by rheumatic disease, and the lack of facilities for adequate treatment, have sent delegations to continental centres to study the work done there. The organisation of these continental clinics is usually excellent, and arrangements are made for the treatment of labouring men and women after work hours. The results are good and often lead to a resumption of work which had become impossible. It was clear that a series of such clinics could do much to diminish the rheumatic disabilities in this country, and the British Committee on Rheumatism proposed to the British Red Cross Society that an appeal should be made for funds to equip the first clinic of the series. An appeal for £40,000 was accordingly made, and the sum was rapidly subscribed, their Majesties the King and Queen heading the list. When two-thirds had been collected Sir Otto Beit guaranteed the remainder; the approved, friendly, and benefit societies, and members of the Stock Exchange and various banks also contributed. The Prudential Assurance Society gave all the linen and towels.

The Building.

In considering the site, a central position easily accessible by omnibus and train was desired; the disused Baptist Chapel between Park-square East and Peto-place fulfilled these conditions, and was also spacious and soundly built. On the plans of Mr. T. A. Pole it was converted into a modern clinic equipped with every recent form of apparatus for the treatment of rheumatism. The costs of construction and equipment have been covered by the interest on the appeal fund, and the capital remains intact. The clinic will have a definite scale of charges depending on the income of the patient. The third floor is reserved for the treatment of well-to-do patients, whose fees will help to support the rest of the clinic. The lower floors will be used for patients who cannot afford high fees, but whose doctors have recommended them for treatment. Members of approved societies will be charged on a special scale, 3*s.* for a single treatment and 25*s.* for a course of not less than eight treatments. Other patients will be charged whatever fee is thought suitable by the lady almoner when she has assessed their incomes.

Staff and Arrangements.

The staff of the clinic includes 11 honorary consulting physicians, five honorary visiting physicians—Dr. M. B. Ray, Dr. F. D. Howitt, Dr. C. B. Heald, Dr. B. S. Nissé and Dr. W. S. C. Copeman—a medical superintendent, Dr. A. R. Neligan, and a sister-in-charge and lady almoner. The actual treatment is to be conducted by a skeleton staff of masseuses and nurses at present until the extent of the work becomes stabilised There is accommodation for between 300 and 400 patients a day, but a larger staff will, of course, be necessary before so many come under treatment. It is estimated that each masseuse can treat 15 patients a day, on an average, provided that at some points she can have two patients under treatment at the same time; to take an example, one patient can be massaged while another patient in the same room is being treated with radiant heat. The clinic will be run entirely for out-patients and treatment will be given by appointment, so that no patient need be kept waiting. On three nights of the week the clinic will remain open until 9 P.M. to give men and women of the labouring classes an opportunity to come for treatment when their work is done; men and women are to be treated on alternate days.

Ground Floor Accommodation.

The accommodation for treatment is spacious and attractively arranged. Upon entering, well-to-do patients go at once to the third floor by lift, while others pass through the admission office and thence to the lady almoner. They are next interviewed and examined by the physician, and treatment is prescribed; after making an appointment they leave and return at the required time. If they are to receive bath treatment they pass to a series of cubicles supplied with seats and mirrors, where they undress and put on a specially designed bathing dress which leaves the back and limbs uncovered. They pass without waiting to another series of cubicles containing showers and foot baths, and then straight on into the room where they receive treatment. This is fitted with whirlpool, douche, and needle baths, and with Vichy, Aix, and Buxton installations. These rooms are arranged round a circular central court which plumbs the whole depth of the building and is lighted by a glass dome above. In the centre of this court is an immersion pool about six or seven yards in diameter, divided by three partitions so that each portion can be used for a different treatment if necessary. The compartments are fitted with steps and teak seats on which the patient sits while receiving manipulative treatment under water, or while performing exercises in voluntary movement. Undercurrent douches can be given through special pipes. On this floor there is also a hot air room and a vapour bath. After treatment the patient receives a hot bath sheet and lies down on a couch in the rest room before returning to his cubicle to dress.

Upper Floors.

On the second floor is the main consulting room, with an adjoining examination room fitted with cubicles and a couch, staff rooms, the secretary's office, and the office of the sister-in-charge. These also are arranged round the central court, along a corridor which leads also to the treatment and massage rooms. Each of the treatment rooms is equipped with its full complement of electrical, radiant heat, ultra-violet light, and diathermy apparatus, so that any treatment prescribed can be administered in any given room by a single masseuse, and there is no occasion for the patient to pass from room to room or into different hands. Two such rooms completely equipped are at present ready for use, with curtained cubicles at hand in which the patient can undress.

After treatment the patient passes to a cooling-off room and rests before dressing. There is also equipment on this floor for treatment by Plombière lavage, which is installed in a separate room. The third floor, which is devoted to the better class of patient, is supplied with all the same apparatus as the other two floors. Besides treatment rooms it has its own immersion bath, whirlpool, undercurrent douche, and needle baths, and includes a lounge where patients can wait if necessary. There are also vapour and hot air rooms, and accommodation for an X ray apparatus should it become desirable to instal one. It has been decided to use softened Thames water rather than imported or artificially prepared waters, in the belief that heat and immersion are largely responsible for results rather than the composition of the water.

The conditions to be treated are as follows. Chronic rheumatic diseases, such as chronic articular arthritis, spondylitis, and gouty arthritis; also lumbago, muscular rheumatism, sciatica, and fibrositis, muscular weakness due to paralysis, neuritis, neuralgia, and the sequelæ of injury to or inflammation of joints, muscles, tendons, bones, and nerves—a wide programme. It is hoped to make the clinic a centre for research, and a laboratory is at the disposal of the staff. Treatment will begin by about the middle of the month.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Hospitals and Sweepstakes.

LAST week the Dail gave a second reading to a Bill, introduced by Sir James Craig, designed to legalise the holding of sweepstakes and lotteries for the support of hospitals and sanatoriums in the Irish Free State. Sir James made it clear that he was not enamoured of this method of raising money, but he had been forced to believe that unless funds could be raised in the near future some of the hospitals might have to close their doors, and he knew of no other means by which the need could be met. He gave detailed information on the financial position of certain Dublin hospitals. The measure was left to the free vote of the House, and only six deputies were found to vote against it. Among these was President Cosgrave, who, sympathising with the difficulties of the hospitals, pointed out that the measure, if passed, would constitute a precedent on which those interested in other charitable projects could build a case for other exceptions to the Lottery Acts. The proposal has received a certain amount of opposition outside the Dail. In particular, the Archbishop of Dublin, in a sermon on gambling preached last Sunday, deplored the measure, and the facilities given to it by the Dail. His condemnation was based on moral grounds, but he added the pertinent observation that one inevitable reaction would be that those hospitals which resorted to questionable methods of finance would cease to awaken the same sympathy in the breasts of voluntary subscribers as they had done in the past.

Complimentary Dinner to Dr. W. W. Murphy.

Dr. W. W. Murphy, of Coolgreany, Co. Wexford, has been honorary secretary of the County Wexford Medical Practitioners' Association for some thirty years. During that time his energy and common sense, his tact and courtesy, succeeded in keeping the profession of the county a singularly united and harmonious body. The high respect in which he was held in the county gave him an added influence in his dealings on behalf of the profession with the various local authorities. It was fitting, therefore, that his fellow practitioners should, on the occasion of his resignation of the office of honorary secretary, show their gratitude and friendship for him in some definite way. They therefore entertained him to dinner at Bennett's Hotel, Enniscorthy, last week, and presented him with a handsome clock as a token of esteem. Dr. G. E. J. Greene, of Ferns, presided over a company of more than half the medical men in the county, and apologies for absence were received from all those whom distance or other causes prevented from attending. Dr. W. C. Lawler, in a speech in honour of Dr. Murphy, said that if he were asked by a young man starting his medical career for a bit of grandfatherly advice, he would say: "Show consideration, respect, and loyalty to your fellow medical men." Whatever of that advice he himself practised he owed to the inspiration and example of Dr. Murphy. Medical men outside County Wexford are glad to note the compliment paid to Dr. Murphy by his immediate neighbours. He has been an active member of the several Irish medical organisations, and is held in respect and friendship by all who know him.

Dublin Slums.

It is disconcerting to learn that, in spite of the amount of building in Dublin and its neighbourhood in the last ten years, the problem of the Dublin slums is greater than ever. Speaking at the annual meeting of the Incorporated Orthopædic Hospital last week, Dr. M. J. Russell, medical officer of health for the city of Dublin, said that there were more unsanitary rooms and dwellings in Dublin to-day than at any time in its history. There were kitchens occupied at present that had been closed in his predecessor's time.

Condition of Poor-law Institutions in County Clare.

A recent report by one of the medical inspectors of the department of Local Government and Public Health, Dr. A. D. Clinch discloses a shocking condition of several of the institutions under the charge of the Board of Health for County Clare. Of the Ennistymon District Hospital, containing 22 patients, he says: "This building is hardly fit for habitation. It is without any inside sanitary conveniences, and is a danger both to patients and staff. It should be closed until a new hospital is provided." Of the County Nursery, with 61 patients, he says: "All the buildings are in a very bad state of repair; the roofs are leaking; the laundry is of the worst type; there are no baths, no inside sanitary accommodation, no disinfecting apparatus, and the staff are working under great difficulties." The County Home, containing 412 infirm patients, has no inside water-closet in the body of the house, and "the necessity for the complete reconstruction of the home is very urgent." When the report containing these statements was read to the board no action was taken.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Edinburgh Orthopædic Clinic.

AT the new Settlement in the Pleasance, one of the most overcrowded areas of East Edinburgh, the executive committees of the Pleasance Trust and the Chartered Society of Massage and Medical Gymnastics have established an orthopædic clinic. The whole settlement has as its superintendent the Very Rev. J. H. Miller, D.D., ex-Moderator of the United Free Church. Dr. Miller's social work is one of the great things in Scotland. Nothing is foreign to him, and he has done everything to bring about the association of the settlement with child welfare work and orthopædic work, including all that is connoted by "remedial gymnastics." At the opening, Miss Gertrude Herzfeld, Surgeon at the Sick Children's Hospital, explained that the work at this clinic had been inaugurated by members of the Chartered Society of Massage and Gymnastics because they felt that there was too big a gap between the work at the hospitals, which was given entirely free, and the work done by the private masseuse, for which the ordinary fees were necessarily high. The masseuses had decided to start a clinic for people of limited means who wished to pay but could not afford the full fees, and by the kindness of the Pleasance Trust they had been allowed to start it in the Pleasance. The clinic was meant to be self-supporting. Patients were as a rule recommended to come by their own doctors, and the work was done under medical supervision.

Housing Improvements in Edinburgh.

The new housing improvements proposed for Edinburgh involve the provision of 1557 houses for displaced tenants, and the scheme is the largest of its kind ever undertaken by the Corporation. The total cost would be about £854,000, which amounts to about a penny per pound on the rates. The reports of the medical officer of health, the burgh engineer, and the sanitary inspector furnish abundant justification for the Corporation's action in framing the proposals. The general death-rate per 1000 for the area is 19, as against 14·3 for the whole city. The pulmonary tuberculosis death-rate is 1·3, as against 0·9 for the city. The death-rate for other forms of tuberculosis is 0·7 for the area, as against 0·3 for the city, and the respiratory diseases death-rate is 4·2 for the area, as against 2·2 for the city. The infantile mortality is 120, as against 84 for the city. Under five deaths were 36·2 per cent. of total deaths, against 17·1 for the city. These facts are reinforced by the details of overcrowding. The sanitary inspector quoted cases of common stairs which included from 29 in one case to 49 "houses" in another, and provided accommodation for from 107 to 119 people. That, he said, made decent and healthy living impossible. The stairs were of the spiral variety, and were so dark as to be dangerous.

The area chosen contains some of the oldest houses in Edinburgh. It was on passing some of these that Edmund Parkes said that these were not houses but villages standing on end. Those ancient and ill-constructed tenements are the supreme difficulty of the great Scottish cities. In the new schemes the Corporation intends to take care that the general historical landmarks shall not be too seriously interfered with. This area of St. Leonards has been crying for improvement for two or three generations. The success of the other Edinburgh housing schemes has, no doubt, had an influence in inducing the Corporation to make this great further effort.

The Blind of Dundee.

The Dundee and Lochee Mission for the Outdoor Blind are peculiarly fortunate in receiving under the will of the late Sir James Duncan, of Coupar Grange, Perthshire, a sum amounting to £59,901. Within the last ten or twelve years the whole problem of the blind has been placed on a much more satisfactory footing. One does not know the conditions of this large bequest, but it seems a pity that the money could not be controlled by some central body in the interests of the Scottish blind as a whole, or even of the Dundee blind as a whole. The problems of work and teaching have given a great deal of trouble to the authorities, but those problems are working towards a satisfactory solution. Under the Statute, the Health Department for Scotland is guided by a large Advisory Committee, which includes general and technical members. No doubt the developments in Dundee will be supervised in such a way as to ensure that this relatively large sum shall be equitably administered.

Glasgow Corporation Lectures.

Prof. John R. Currie, of Glasgow University, in a recent lecture on Infection and Progress, gave some striking instances of how disease disappears not from direct attack but incidentally as a result of social movements. He referred to two forms of infection as of special importance. The two principal ways in which infection spreads were, he said, by spray from the mouth in the act of speaking or coughing, and by blood-sucking insects. Medical and social progress had consistently warred on the process of infection, but one result of each movement for the betterment of the people was that certain diseases had been extinguished in this country long before medicine had discovered their causes or found specific methods of control.

The return by Dr. Pratt Yule, the county medical officer of Fife, states that 335 cases of tuberculosis were notified in the county during 1929, that 315 were confirmed, that the number of known cases on Dec. 31st was 911, and that the number of cases in institutions was 97.

At the annual meeting of the Edinburgh Juvenile Organisations Committee Lord Linlithgow commended strongly the work of the association, and put emphasis on the need for careful case-recording. This organisation acts as a clearing-house for the societies affiliated with it. But it also does direct work. It keeps close touch with the police-courts and with the sheriff court.

Correspondence.

"Audi alteram partem."

THE MECHANISM OF PULMONARY COLLAPSE.

To the Editor of THE LANCET.

SIR,—Why do not open wounds of the visceral pleura involve collapse of the lung? In your leading article last week on Surgical Access to the Chest reference is made to recent discussions involving answers to this question, as well as to Sir John Rose Bradford's valuable address on Massive Collapse of the Lung. May I explain what appears to me to be the solution of this and many other problems arising out of various clinical phenomena?

It is over thirty years ago that I first directed attention to the clinical importance of the physiological rhythmical dilatation and contraction of the bronchioles.[1] In utero the lungs of the full-time child are solid and the trachea and bronchi are collapsed, or any potential space is occupied by secretion. At birth the dilatation of the nostrils and glottis aid free inspiration and this air soon occupies the trachea and larger bronchi. The contraction of the glottis on expiration impedes the escaping breath, hence the air is in part retained, only to be increased in volume at the next breath. This rhythmical dilatation and contraction of the nostrils and glottis is associated with corresponding rhythmical dilatation and contraction of the bronchioles, which get quickly filled and overfilled and thus the alveoli too become filled with air.

The same physiological rhythmical dilatations and contractions of the bronchioles ensure the continued full dilatation of the pulmonary vesicles against the contractile force exercised by the elastic fibres in the lung, and thus, too, under normal conditions the air pressure and oxygen tension in the vesicles is maintained. Consequently, a shell wound ripping open the chest wall and its parietal pleura is not followed by collapse of the lung, provided the visceral pleura remains intact. Hence, too, the surgeon operating for empyema need not fear to open the chest wall and parietal pleura even in the absence of adhesions between the pleural layers, provided the visceral pleura is uninjured.

On the other hand, a minute perforation (very much smaller that the glottis) of the visceral pleura results in acute pneumothorax, the lung collapses unless, of course, adventitious adhesions suffice to prevent this otherwise inevitable sequence. Once collapsed, the minute perforation of the visceral pleura usually soon heals and closes, and then again the physiological rhythmical dilatation and contraction of the bronchioles will make that lung dilate up and reoccupy the normal space belonging to it in the chest. This but repeats what caused that lung to dilate at birth and become a normally distended lung.

---

[1] Encyclopædia Medica, 1st ed., vol. ii., 1899, p. 117, and Bristol Medico-Chirurgical Journal, March, 1903, on the Probable Rhythmical Contraction of the Bronchial Muscular Coat as a Factor in Pulmonary Disease.

If my theory is correct this rhythmical dilatation and contraction of the bronchioles explains why it is that sometimes distension of the pulmonary alveoli occurs beyond the site of obstruction by a close-fitting foreign body like a bean in a bronchus. Inspiratory dilatation allows the air to pass into the bronchus past the bean, but on expiratory contraction the bronchiolar muscle clings so tightly to the surface of the bean that no air escapes, or at any rate less than was inspired into that pulmonary area.

I am, Sir, yours faithfully,
PATRICK WATSON-WILLIAMS.

Clifton, Bristol, Feb. 24th, 1930.

"A PERNICIOUS TYPE OF ANÆMIA."

To the Editor of THE LANCET.

SIR,—Dr. Avery's report on a pernicious type of anæmia following erythræmia, appearing in your issue of Feb. 15th (p. 342), presents points of great hæmatological interest. Is it not, however, time that the term "pernicious type of anæmia" be discarded? It is, I think, commonly agreed that the essential hæmatological characteristics of pernicious anæmia are: reduction in the number of red corpuscles, with a high colour-index; leucopenia; and relative lymphocytosis, together with an invariable megalocytosis. In Dr. Avery's case the leucocytes were never below 8000 per c.mm., and at this time the lymphocytes were 6·67 per cent. Then again, as Addison was the first to point out, emaciation does not occur in pernicious anæmia, whereas Dr. Avery's post-mortem report states that the body was wasted. The indefinite character of the ferro-cyanide reaction in the spleen is certainly an unusual finding in the typical disease. It seems that the only reason for regarding the anæmia as being of pernicious type is the fact that the patient improved when given half a pound of liver daily.

I find untenable Dr. Avery's explanation of anæmia due to excessive irradiation as being the result of destruction of erythropoietic tissue and impairment of the hæmolytic function of the spleen. Mayneord and Piney (*Brit. Jour. Rad.*, 1928) showed an extreme degree of hæmosiderosis in the spleen of rabbits that had been exposed to large doses of X rays. Furthermore, in cases of chronic myeloid leukæmia with severe secondary anæmia irradiation of the bones only is often followed by reduction in the number of leucocytes and a rise in the number of red corpuscles.

May I in conclusion express my gratification that there still remain writers who, in spite of the modern fashion, will publish accounts of singular cases of such great interest as the one under discussion.

I am, Sir, yours faithfully,
A. PINEY.

The Cancer Hospital, Fulham-road, S.W., Feb. 21st, 1930.

REST IN THE TREATMENT OF GONORRHŒA.

To the Editor of THE LANCET.

SIR,—Dr. Byles's insistence on the importance of rest in bed in gonorrhœa cannot be too strongly emphasised. Surely, however, the time has hardly yet come when "the onus of refusing to lie up must be put on the unhappy victim." "Propaganda and leaflets" may, as Dr. Byles says, have "made these complaints a subject of ordinary conversation in mixed companies," but in the previous sentence he admits the "still persisting taboo, disgrace, and secrecy" involved. There are few walks of life in which the required rest in bed can always be carried out without disclosing the real nature of the illness, sooner or later. The routine treatment of gonorrhœa in the Army V.D. hospitals wisely includes compulsory rest in bed during the acute stage of the disease, and this is of psychological as well as physical importance in bringing home to a man the necessity of taking the disease seriously.

May I also briefly refer to Dr. Sequeira's letter of Jan. 18th on compulsory treatment of V.D. and the rejection by Parliament of various Bills thereon? In approving its action, he dwells entirely on the debatable ground of the relative curative value of salvarsan, but surely the case for compulsory treatment rests as much on the fact that salvarsan therapy is the quickest and most efficacious method of rendering a patient non-infective to others as on the permanency of the cure of the individual.

I am, Sir, yours faithfully,
W. H. DICKINSON PRIEST,
Late M.O. i/c Venereal Diseases,
British Army of the Rhine.

Royal Waterloo Hospital, Feb. 24th, 1930.

HOUSING AND RHEUMATIC DISEASE.

To the Editor of THE LANCET.

SIR,—Environment is certainly an important factor in producing the rheumatic diseases, including rheumatoid arthritis, which are responsible for a large amount of invalidity in this country. R. H. Miller has indeed remarked that environment, taken as a whole, is of such importance that rheumatism may be regarded as an environmental disease. Of these environmental conditions housing occupies the first place, and a survey of housing since the end of the great war throws much light on this subject. The shortage of houses at the end of the war necessitated rapid erection. Wooden houses at first took the place of more permanent structures, and this was followed by the adaptation of army huts. Then came jerry-built houses of cheap brick with walls of minimum thickness, ready made staircases, doors and window-frames of unseasoned wood. Foundations were laid with inefficient ventilation, no tongue and grooved boarding was used for flooring; in low lying districts houses were built on marshy soils without efficient draining. One can picture what must be the condition of clothing, bedding, and furniture in such houses, and how the sweating plaster, the ground gases passing between the floor boards, the timber warping and leaving spaces for the admission of damp must affect the health of the inhabitants.

These new houses are, I believe, a definite cause of rheumatism and fibrositis. Rheumatism may be induced in an individual living in one district, whereas in another district not many miles away he may be quite free from pain and inconvenience. There are, for instance, two places in the Thames valley within easy reach of London less than a mile apart but separated by the river. In one of these districts rheumatism is almost unknown, while in the other it is extremely prevalent. The former is flat with gravel soil and a limited number of trees. It is on the level of the river. The latter abounds with trees, has a heavy loam and gravel soil, and is 40 feet higher than the river. They have the same water-supply, and the climate is identical. A man well known to me removed from the former to the latter, and within a few weeks could only roll out of bed in the mornings. Six months later he moved back again on account of the rheumatism which had become so severe. Within two days he could rise in the mornings without discomfort, and except for a few fibrous nodules the rheumatism disappeared. In another district 250 miles from London rheumatism is very prevalent. This district is flat with the subsoil water only a few inches below the surface; there are few trees and the town is bleak and windswept. It is surrounded by miles of flat marshy land and is at sea-level. At one point where numerous dwellings abound the subsoil water is 4 inches from the surface; ground gases are most prevalent. The soil is sandy and the water-supply is derived from artesian wells, the water being very hard. The climate is mild and the sea breezes are gentle and often of a sultry humid character.

Facts such as these have led me to believe that the production of rheumatic disease is largely determined by living in houses with damp subsoil and damp rooms, and, by exposure to cold and wet climatic conditions.

I am, Sir, yours faithfully,
FRANK RADCLIFFE.
Harley-street, W., Feb. 23rd, 1930.

A DERMATITIS FROM FACE POWDER.

To the Editor of THE LANCET.

SIR,—Recently a spinster, aged 41, consulted me regarding an inflammatory condition on both cheeks. It was practically restricted to the malar area. She stated that the trouble had appeared four times during the last three months. Heat, burning, redness, and much discomfort followed on each occasion she had applied a rouge powder to tint this part of her face. The same powder had been used by her occasionally, in exactly the same manner, for a number of years without the least inconvenience. Upon examination, besides the very evident inflammatory zone on the cheeks, the flush areas, forehead, chin, and nose, showed well-marked early stage of rosacea. This condition, the patient thought, had only appeared recently. The face powder was kindly examined for me by Mr. T. H. Byrom, F.I.C. It contains carmine, chalk, but is chiefly made up of angular transparent particles and a few spicular bodies. The two last are certainly silicates. The diagnosis was: numerous traumata upon a developing rosacea.

It would interest me to know if others of your readers have come across this distressing dermatosis. This patient had seen her own medical man two or three times for this complaint, without getting any relief. A lip salve containing eosin has been mentioned by Audry and Valdigue as having occasioned objectionable injuries; but I do not remember having seen reported acute eruptions caused by face powders. If they do occur, are they usually associated with the angio-neurotic changes which take place on the face of some women in middle life?

I am, Sir, yours faithfully,
Wigan, Feb. 20th, 1930. R. PROSSER WHITE.

THE CASE AGAINST THE WIDAL TEST.

To the Editor of THE LANCET.

SIR,—In your editorial article of Feb. 1st on the Case against the Widal Test you mention that while "O" antigen gives rise to "O" agglutinin "H" antigen gives rise to both "O" and "H." This statement is surely at variance with modern opinion, which generally maintains that there are two classes of antigen "each stimulating *in vivo* its own antibody with which it exclusively reacts."[1] The confusion has apparently arisen in the use of the letter "H" which, first applied to a certain (*Hauch*) type of growth, was subsequently used to denote the particular antigen, "H" giving rise to the floccular agglutinin. It is also stated that "in inoculated persons the anamnestic reaction is accompanied by 'H' not by 'O' agglutinins." This statement apparently rests on Felix's assumption that the blood of inoculated persons (in any condition other than enteric infections) does not contain "O" agglutinin in greater titre than 1 in 100, and consequently anything over this titre is an absolute indication of an enteric infection. Felix's assumptions have been recently discussed and criticised by Gardner,[2] who points out that such a "threshold" titre is purely empirical and depends to a considerable extent on the technique employed by Felix.

The fallacies of the ordinary quantitative Widal are so notorious in the tropics, where inoculation is largely used, that special interest has been taken here in the qualitative receptor analysis of Felix, and for the past year in these laboratories both methods have been followed in parallel (an alcoholic bacterial emulsion being used for the "O" antigen). The results so far obtained have been in complete agreement with those of Gardner, the "O" agglutinin in healthy inoculated individuals and in inoculated persons suffering from some non-enteric condition (malaria, kala-azar) rarely exceeding a titre of 1 in 200. On the other hand, in an inoculated person suffering from true enteric (*B. typhosus* isolated from the fæces) the serum taken on the tenth day showed the following "O" titres: T 50, A 0, B 50 ("H" agglutinins were absent). Owing to the distance of the patient from Khartoum further estimations were impossible.

In my experience titres of "O" agglutinin of more than 1 in 125 in any enteric case appear to be rare for the first 10 or 12 days of the fever, and as it is impossible in many cases in natives to ascertain whether they have received previous TAB. inoculations or not, the qualitative method has so far proved (in many cases) to be just as inconclusive as the ordinary quantitative method, and while giving valuable assistance cannot supplant the standard method.

I am, Sir, yours faithfully,
E. S. HORGAN,
Assistant Bacteriologist, Sudan Government.
Khartoum, Feb. 15th, 1930.

PSITTACOSIS.

To the Editor of THE LANCET.

SIR,—Further investigations with the organism which I recovered from the blood of our patient A. B. (one of the Warwick cases of this disease, described in my previous letter)[1] would point to its being nearest to *B. fæcalis alk.* It is certainly not a salmonella. The patient herself is now quite convalescent. On Feb. 12th—that is, six days after the temperature had returned to normal—I put up her serum against the typhoid group, salmonella, and her own bacillus. Whereas I got entirely negative results with the first two, her own bacillus was very definitely agglutinated down to dilutions of 1 in 125.

I am, Sir, yours faithfully,
A. T. W. FORRESTER,
Medical Superintendent,
Feb. 25th, 1930. Warwick County Mental Hospital.

VOLUNTARY HOSPITAL NURSING HOMES.

A PRACTICAL PROPOSAL.

To the Editor of THE LANCET.

SIR,—The voluntary hospitals of London provide over 12,500 general ward beds and 1250 pay-beds for the patients of London day by day throughout the year, and the public response to meet the cost of reconstruction and modernisation since the war has been so great and so generous that I venture to make a practical proposal with regard to the endowment side of hospital work which could be effected without appeal to the public. It is a simple business proposal, and it is suggested in the reference made by H.R.H. The Prince of Wales at the last annual meeting of the King's Fund to the subject of pay-beds.

The proposal is for the existing paying patients' beds to be increased from 1250 beds to 2500 beds, with the status of "Voluntary Hospital Nursing Homes," for the admission, not only of those of small income who are able to pay a contribution towards the cost of maintenance, but also for those of better means whose present resource, in case of serious illness, is a private nursing home at charges ranging from 8 to 12 guineas a week, with extras. By a simple calculation it can be shown that with an inclusive charge ranging from 4 to 10 guineas, an average of 7 guineas a week or possibly less, the surplus income beyond the actual cost of maintenance would (subject to the capital arrangements referred to later) be sufficient to pay off the capital expenditure in about three years. The proposal needs the assistance of the Unemployment Grants Committee—a Government committee appointed to make grants for work that will give employment to unemployed men from the mining districts—without which the period of redemption would be longer.

---

[1] THE LANCET, Feb. 8th, 1930, p. 323.

Let me give an example, an actual instance of a hospital with 100 general ward beds which needs 25 beds for paying patients—a capital outlay of £25,000. The usual contribution by the Unemployment Grants' Committee would be £15,000 and the contribution by the hospital, by means of a loan, a sum of £10,000. The surplus income from the pay-beds, with an average charge of 7 guineas a week, would amount to a sum of £3500 a year—i.e., sufficient to pay off the hospital loan of £10,000 in about three years. The hospital will have become possessed of 25 beds for paying patients, the surplus income of which, when the loan has been repaid, will be sufficient to pay the cost of maintenance of 25 beds in the general wards of the hospital.

The proposal could be carried out on an average charge of less than 7 guineas a week, but the period of redemption of capital would be proportionately longer. I believe, however, that whatever charge is found most workable, the suggestion is one which would be welcomed by a very large section of society, especially those interested in hospital work, who would be likely to prefer to send their family to the nursing home attached to the voluntary hospital in which they are interested. The charge would be less than they would pay in a private nursing home, and there would be the added inducement that they would be contributing towards the permanent endowment of a general ward bed in the hospital in which they are interested.

The general result would be that within the next year or two the paying patients' beds throughout London could be increased from 1250 beds to 2500 beds, and three or four years later, when the capital charges have been paid off, the surplus income from the beds would then be available permanently to provide the entire cost of maintenance of 2500 general ward beds for the wage-earning class—without cost to the hospital and without appeal to the public.

I am, Sir, yours faithfully,
A. BRUMWELL THOMAS.

F.3, Albany, Piccadilly, W., Feb. 22nd, 1930.

WE regret to record that Mr. ARCHIBALD R. FEE, Ph.D., died on Feb. 23rd. He was a keen and devoted investigator in experimental physiology, on which he was working at University College, London, with the aid of a Beit Memorial Fellowship for Medical Research. Though only 24 years of age at the time of his death, he had already made considerable contributions to the physiology of the kidney, and some of these papers will appear posthumously. His ambition and determination was to qualify in medicine, and he had already begun some preliminary studies directed to that end. Dr. Fee's home was in British Columbia, which he left with a University degree before he was 20 years of age.

A LEWES HOSPITAL FUND.—Inaugurated in the Sussex county town six years ago by the then Mayor, Alderman W. Canadine, a hospital penny fund, covering the borough of Lewes, and a number of parishes around, had a record year in 1929 when £925 was collected. Of this sum £815 was paid to the Lewes Hospital, and £66 to Brighton hospitals. There are nearly 5000 subscribers to the fund.

Obituary.

ALFRED HERBERT TUBBY, C.B., C.M.G., M.S., M.B. LOND., F.R.C.S. ENG.,

CONSULTING SURGEON TO THE WESTMINSTER HOSPITAL.

WE regret to announce the death of Mr. A. H. Tubby, consulting surgeon to the Westminster Hospital and for many years a well-known authority on orthopædic surgery and the surgical diseases of childhood. Mr. Tubby died on Sunday last, Feb. 23rd, in a nursing home, at the age of 67. He had but recently retired from active practice.

Alfred Herbert Tubby was born in 1862, the son of Alfred Tubby and his wife, who was a Miss Frances Roe. He received his education at Christ's Hospital, and entered as a medical student at Guy's Hospital, where he immediately started a distinguished scholastic career, as he obtained prizes at his own medical school and also the gold medal in medicine in the examination for the London degree of M.B. and the gold medal in surgery in that for the B.S. degree. He proceeded to the M.S. in London and in 1887 obtained the F.R.C.S. Eng. He early showed his bias towards orthopædics by appointments at the Evelina Hospital for Children and the Royal National Orthopædic Hospital in 1892, and when two years later he was elected assistant surgeon to the Westminster Hospital, this branch of surgery remained his particular subject of interest.

MR. TUBBY.

[*Photograph by Elliott & Fry.*

He pursued studies at different intervals as occasion offered at Halle and Leipzig, and as a result he published in 1906 the first version of his well-known text-book on Surgical Deformities. This work was a departure in English and confirmed his position as an orthopædic surgeon, but the later version entitled "Deformities including the Diseases of the Bones and Joints," which appeared in 1912, was largely a new book. For during the intervening 16 years the progress of orthopædic surgery had been very large and varied, and so much rewriting was found necessary that the work may be regarded as a new one. The opportunity of rearranging the subjects was also fully taken so as to group together conditions which are allied ætiologically and pathologically, while assistance to the reader was provided through profuse illustration by plates and figures, many of them being original. For this book the author received great credit, and it is noticeable that in the many arguable points both in causation and treatment which a vast subject entailed upon him, Tubby, while giving full value to personal opinions derived from great experience, was fair in his judgments. The lavish employment of pictures undoubtedly increased the utility of a valuable text-book.

On the outbreak of the European war Tubby was attached as consulting surgeon with the rank of Colonel A.M.S. to the British Mediterranean Expeditionary Force, and from 1915 to the end of the war served with the Egyptian Expeditionary Force, being mentioned three times in despatches and receiving the honours of C.M.G. in 1916 and C.B. in 1918. His story of the Gallipoli Campaign appeared in 1921, and gave a graphic picture of the sufferings of the troops and the sanitary difficulties which had to be surmounted or endured.

While Tubby's name is chiefly associated with his orthopædic work, he was a good general surgeon, and in that capacity, though having the particular care of his specialty, he acted as surgeon, and later consulting surgeon, to the Westminster Hospital for no less than 36 years, for 30 of them as full surgeon in charge of beds. His association with the Evelina Hospital was even longer, and at the Orthopædic Hospital he worked for a generation, and he thus acquired a particular interest in, and knowledge of, the diseases of childhood, which took expression in the foundation, with the late Mr. Sydney Stephenson, of a society for their study, which is now represented by a Section in the Royal Society of Medicine, over which in 1912 Tubby presided. He was president of the same section at the meetings of the British Medical Association on two occasions—namely, in 1907 and in 1921. He was recognised outside his own country as a pædiatrician, being a member of several French scientific societies and also of the American Orthopædic Association. Although mainly known as an author of one great text-book on his own specialty, he collaborated with Sir Robert Jones in a book on the surgery of paralysis and, as President of the Hunterian Society, he delivered the Society's annual oration upon similar lines. He was a frequent contributor to our own columns, when his clinical papers were always marked by clearness and accuracy, and a series of articles, which had appeared in the *Clinical Journal* made up the main contents of a small volume, entitled "The Advance of Orthopædic Surgery" which appeared in 1925. In 1928 he wrote his last article for THE LANCET, which well illustrated a practical side of his activities as an operating surgeon. This was a series of close observations on the selection and stardardisation of surgical instruments profusely illustrated with microscopical sections of knife-blades in exemplification of their hardness and of the influence of the processes for rendering them stainless. His main conclusion was that the employment of stainless steel instruments in surgical and dental procedure is warranted, as the obvious advantages of economy of time and labour are not accompanied by any loss of hardness.

Sir Robert Jones writes:—"For nearly forty years my old friend, Alfred Tubby, and I have worked together and played together in close companionship. He was delightful both in his study and in the country. It is rare indeed to meet with so much culture in a man who has had to struggle against so many obstacles before arriving at eminence. He was a great reader of the best literature, and proved an inexhaustible storehouse of rare knowledge. He travelled much with a closely observant mind and was quite an authority upon European history; an excellent linguist, nothing escaped him when abroad, and he revelled in the companionship of guide and peasant. He loved the Alps, and more especially the peaks of the Austrian Tyrol in chase of chamoix. His reminiscences of such adventures were always brilliantly recounted. For many years we shared a shoot in Prussia in the midst of deer and wild boar, and stayed with a mutual friend and landowner, Robert Tudor. Many a winter evening we spent in close intimacy by the fireside listening with delight to Alfred Tubby on the habits of animals and his experiences of travel. He was a lovable character, loyal in friendship, and full of understanding. To many he may have appeared aloof and reticent, and even unsympathetic, but this was a veneer covering a very kindly heart."

A professional friend and colleague writes:—"Mr. Tubby held a place in orthopædic surgery in this country that was in some respects unique. He was old enough to be familiar with the traditions of pre-antiseptic days—the days of 'tenotomies'—and young enough to play a large part in the transit of orthopædics from the shadow of cantilevers and turn-screws into the light of operative day. While still at Guy's hospital he had done some research work both in neurology and on the repair of tendons, and he was always alive to the possibilities of clinical research. He was avid of suggestions for modifications of practice, and eager to put them to trial, though he had the strength of mind to drop forthwith those which seemed to him unfruitful or dangerous. He had a flair for the selection of mechanical apparatus and a craftsman's eye for the detection of defect and the economical provision of a remedy. His operative technique was sound, the work patient and painstaking, and he spared no trouble in following up his cases and extracting the utmost possible out of what he had done. He was a sound teacher, never overloading his subject with detail. He possessed a remarkable memory and an enormous experience. He remained a general surgeon to the time of his retirement, but his reputation in orthopædics had brought him a world-wide connexion and his wards were therefore largely filled with bone—joint—and deformity cases. He was a man of keen business instincts, and as dean of the Westminster medical school his services were always of value to the administration of the hospital."

Apart from his professional work Tubby was both an archæologist and sportsman. Taking advantage of his sojourn in Egypt during the war he assisted at excavations which resulted in the communication of papers to the *Bulletin de la Société d'Archiologie*, with the result that he was elected F.S.A. He was a practised mountaineer and wrote on chamois hunting and fishing. A genial and well-read companion, he had, it will be seen, many subjects on which he could and would talk most interestingly.

Mr. Tubby married in 1890 the second daughter of Mr. William Payne, of the Chamber of London, and leaves a widow and one daughter.

Mrs. Tubby was her husband's constant companion, and often shared the joys and labours of his sporting trips abroad.

ARNOLD FRANCIS BILL, M.D. OXF.

Dr. A. F. Bill, whose death from pneumonia in Davos, Switzerland, after only five days' illness, was reported on Feb. 21st, was the son of John Bill, of Coventry, and took his medical course at Oxford University and St. Mary's Hospital, London. He qualified in 1893, going on to the M.R.C.P. Lond. in 1896 and the M.D. Oxf. in 1899. He was house physician and curator of the museum and demonstrator of pathology at St. Mary's Hospital, and was entering on a successful career as physician to St. George's Dispensary in Hanover-square when symptoms of tuberculosis became manifest, and he retired to the Swiss Highlands. With characteristic determination he set himself to take the Swiss Federal Diploma in medicine, a task involving an intimate knowledge of the French language and the ability to pass both preliminary and professional examinations. From 1904 on he practised in Davos, with the exception of two or three years during the war, when he returned to England to take up temporary work as tuberculosis officer in a London borough.

A colleague writes:—"Donnish as to exterior, with a childlike heart, he was often a source of perplexity to his patients, who misinterpreted the far-away look in his blue eyes as a lack of concentration on the immediate necessities of the moment. Latish on, however, after his marriage with Miss Kathleen Fry, he took the position in the English colony which his gifts and his perfect sincerity merited. It is not easily realised by those who have not lived in an Alpine resort to what extent the resident doctor can be their guide, counsellor, and friend, and Bill was never known to fail anybody. He was a consistent supporter of English institutions in the valley, such as the church and library, and was always in demand at social gatherings where children were present, for he had a gift for producing charades and dramatic scenes. He will be much missed."

SIR ALFRED DOWNING FRIPP, K.C.V.O., C.B., M.S. LOND., F.R.C.S. ENG.,

CONSULTING SURGEON TO GUY'S HOSPITAL.

WE regret to record the death, which occurred on Feb. 25th, at his home at West Lulworth, of Sir Alfred Fripp, consulting surgeon to Guy's Hospital, and a prominent figure for many years in the medical and social worlds.

SIR ALFRED FRIPP.

[Photograph by Elliott & Fry

Alfred Downing Fripp was born at Blandford, Dorset, in 1865, being the eldest son of Alfred Downing Fripp, the younger of the two distinguished members of the Royal Water Colour Society whose works are on frequent exhibition in exemplification of Early Victorian art. Alfred Fripp was educated at Merchant Taylors' School and the medical school of Guy's Hospital. A successful student, he graduated at the University of London as M.B., B.S. in 1889, and held the various junior appointments at the hospital, including that of resident obstetric officer. In 1893 he proceeded to the degree of M.S. and obtained the F.R.C.S. Eng., but inclusion upon the staff of Guy's Hospital did not follow until 1899, and during the interval he practised in the country. Upon being appointed assistant surgeon at Guy's he proved himself a good teacher in the medical school, lectured on clinical surgery for many years, and at this period wrote an anatomy for art students, in which he brought his professional equipment into happy conjunction with his practical knowledge of art. He had little or no waiting time in which to make his mark, but was a successful consultant almost from the beginning of his London career, and received a Court appointment unusually soon.

When, in 1900, the South African War broke out, Fripp was appointed Chief Civilian Medical Officer to the Imperial Yeomanry Hospital, and for his services there received the C.B., was mentioned in despatches, and chosen as a member of the Advisory Board for Army Medical Services, whose constitution was one of the outcomes of the prolonged South African struggle and its attendant mishaps. From the Imperial Yeomanry Hospital during the war Fripp wrote for THE LANCET a long and interesting series of communications. In the course of these letters, while the details were given of all the circumstances under which some 2000 patients were cared for from day to day, Fripp wrote a well-informed gossiping summary of the general march of events. In this, like all at home, he was unduly hopeful of an early cessation of hostilities, but he was able to correct a good many false impressions. At the close of the war he was knighted, and in 1906 was created K.C.V.O., and appointed surgeon in ordinary to King Edward VII.

Sir Alfred Fripp became at this period, and later, well known for his public services in connexion with the great London charities. He was a member of the advisory committee of King Edward's Hospital Fund for London, and a member also of the councils of both the Hospital Sunday and Hospital Saturday Fund. To all of these organisations he devoted much energy, and the time was well spent, for Fripp was essentially a man of the world making an excellent personal link between the medical profession and other walks of society. His intimate connexion with theatrical life, shewn by regular appearance at the theatre as a first-nighter, was often used in the cause of philanthropy; similarly an oddly-named association, stated to owe its origin to Fripp, has been the channel of well-directed generosity.

At the outbreak of the late war Sir Alfred Fripp made no secret of his disappointment that the activities of the Advisory Board for Medical Services were not called upon, for his experiences in South Africa would, he considered, have been of tried utility, a utility which might have been increased by his intimate knowledge of public affairs. He was able, however, to play an active part through his immediate appointment as consulting surgeon to the Royal Navy, while in a civilian capacity a large number of seriously wounded passed through his hands. His private surgical practice remained throughout a large and very varied one, but he made few statements in respect of his work at medical societies, and was the author of nothing but one or two scattered papers; the well-written letters from South Africa, as our correspondent, were probably his principal literary output. But the general expressions of regret when the time came for him to sever his active connexion with Guy's Hospital showed how real was the impression he had made upon his colleagues and pupils as an earnest worker for the institution.

Sir Alfred Fripp married in 1898 Margaret, daughter of the late Mr. Thomas Haywood, of Reigate, by whom he leaves two sons and three daughters. Lady Fripp's work on behalf of the less fortunate members of the medical profession and their families is well known to all our readers.

JOHN LLEWELYN-JONES, M.D. LOND.

DR. Llewelyn-Jones, whose death we recorded last week, was 57 years of age, and qualified from the medical School of University College, London, in 1897. He was then house physician and senior obstetric assistant to the hospital, posts which enabled him to take his M.D. Lond. in the minimal interval of a year, and to enter general practice with a solid basis of clinical experience. After a few years in Luton he removed to Gerrards Cross, where the major part of his life was spent. The career of a successful general practitioner does not afford much material for biography. Llewelyn-Jones wrote no medical books; he attended no medical meetings, for his time was always fully occupied in the homes of his patients and at the Cottage Hospital, of which he was one of the founders. His skill in diagnosis was exceptional, and with it he combined the qualities of a fighter—quickness of judgment, resource, determination, and a great courage. He took a keen interest in many forms of sport and one of his friends cherishes the memory of his delight in tramping behind a well trained setter over grouse moors or casting for salmon in a Highland river. Altogether he was a cheery comrade and one who could hold his own in any company. He died as he would have wished, at the height of his activities, his death being due to a pneumonia which early involved both lungs. His work needs no memorial other than the trust and respect which he inspired in a large circle of South Buckinghamshire.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

MENTAL TREATMENT BILL.

(Continued from p. 435.)

Sir BOYD MERRIMAN said he could not agree that the words "incapable of volition," which had been chosen to define the cases in Clause 5, were the best that could be selected. This clause was the heart of the Bill and he did not in the least want to destroy it. He wanted the clause to be read and worked so as to conform with what he understood was the real object of the Bill. The Royal Commission made it a definite recommendation that, on the one hand, it was desirable, in talking about lunacy without giving any rigid definition of lunacy, to adopt a nomenclature acceptable to modern medical thought; and, on the other hand, they said they thought that a greater uniformity of language ought to be devised than was found in the present Lunacy Act. They also pointed out that there was already in the code a large variety of tests or functions of people's state of mind. For instance, there was the main definition of a lunatic as a person, an idiot, or person of unsound mind. There were in various sections differences as wide as this: a person of unsound mind who was incapable of managing himself and his affairs. Another case was that of a person of unsound mind who was incapable of managing his affairs, but capable of managing himself, and was not dangerous to himself or others. In another section was a man of unsound mind, admittedly a lunatic, whose lunacy was in its nature temporary, and would probably soon be removed. That looked like the class of case they were trying to deal with in Clause 5. Again, there was another type of person who, though not found to be a lunatic and not detained as a lunatic, was described as being a person who, through mental infirmity arising from disease or age, was incapable of managing his affairs. With all those definitions no attempt had been made in the Bill to introduce more uniformity into the description of people suffering from unsoundness of mind. They had instead added the entirely new conception of what were called "non-volitional" cases—a particular definition of a class which had never been used before in connexion with lunacy. The phrase really defeated the object of the Bill, because it was impossible to describe people who were said to be incapable of the volition as an intermediate class between voluntary boarders and certifiable lunatics. To him, as a lawyer, incapacity for volition without any limitation at all was indicative of the most complete unsoundness of mind that could be indicated. Absence of volition was the criterion in law for incapacity to contract, to make a will, even, if they liked to be guilty of a crime. They could not describe anybody as being more of unsound mind than to say that he or she was, in every respect, and without any limitation whatever, incapable of volition. Even people who were admittedly lunatics were not necessarily incapable of volition in all respects, but here they were describing this intermediate class, which was supposed to be short of lunacy, as people who were, without any qualification, except in point of time, incapable of volition. There was no limit to it on the face of the words. To talk about removing the stigma of lunacy from people with whom they wanted to deal in this intermediate way and then to describe them as incapable of volition, and leave it at that, was really a contradiction in terms. They were dubbing them for the time being as completely mad in every respect. They had adopted a medical jargon without appreciating all its implications as a matter of law. Mental incapacity to coöperate in a cure did not in the least involve mental incapacity with regard to other affairs. This matter could be dealt with perfectly simply, for the purpose of Clause 5, without stigmatising people as being incapable of volition in all cases, whether for the time being or not, by reversing the wording which was applied to temporary boarders in Clause 1. Instead of dubbing these intermediate people as being incapable of volition, without any qualification whatever, for the time being, they might simply describe them as being people who were incapable of voluntarily submitting themselves to treatment for mental disorder. They would then avoid any question of using a phrase which made them appear to be more mad than the lunatic himself, and which definitely threw a reflection on the patient and on his capacities in any other respect.

Safeguarding the Doctor.

With regard to the protection of medical men, everybody was agreed that it was essential to make it as difficult as possible to attack them in connexion with this procedure. The known reluctance of medical men to certify, because of the risks which attached to it, was a very serious matter in connexion with lunacy proceedings. There was no half-way house between complete immunity for the medical profession on the one side, which had not been seriously put forward, and their liability to be attacked in cases where there was bad faith or negligence. It was in connexion with the provision of safeguards in the latter class of case that the difficulty arose. There was always the risk that a person might be able to get a case on its legs against the doctor. In addition to the real and substantial safeguard provided of going before the judge, who had to be satisfied not merely that there was an allegation of bad faith or of negligence, but that there was sufficient ground for that allegation, he suggested that there should be another safeguard on the analogy of the safeguards which were provided with reference to poor persons' litigation. Before a person was permitted to sue there was an independent committee of investigation. It should be quite possible in the present case, and it would be in the interests both of the public and the medical profession to have a voluntary panel of investigation set up, appointed, if they liked, by the Lord Chancellor and the President of the British Medical Association. There should be some independent body like that to investigate any claim which a person who had been certified desired to bring against a doctor, and make a report to the judge for the assistance of the judge before he was called on to make up his mind whether the proceedings should go on. That was in one sense a matter of detail, but it was of very vital importance. In the interests of the efficient working of the Lunacy Acts, if the doctors could not be given complete immunity they should nevertheless be safeguarded as much as possible.

Reply to the Debate.

Miss SUSAN LAWRENCE (Parliamentary Secretary to the Ministry of Health), replying to the debate, said that it was very seldom that a Bill was received with such general favour as this one. All the points and objections raised were in essence committee points. If there were any better words which would better express the intentions of Clause 5 the Government would be glad to consider them. With regard to the protection of the medical profession, which was dealt with in Clause 16, if they could deal with that matter more satisfactorily in committee well and good; but she very much doubted whether the intelligence of the committee would be able to deal with it any better than had already been done. As to the money which it was stated the local authority ought to have in order to discharge their duty she would point out that that duty was already upon them. Every single person was under care at the moment in asylums or by somebody. The duties imposed on local authorities were permissive. Some local authorities had already passed special Acts of Parliament. The Bill placed other local authorities in exactly the same position as London. It was perfectly true that the Royal Commission said—and the Government had put it in the Bill—that the Board of Control had many imperfections. Dr. Bentham had said that she found the Board of Control very good, but a highly mysterious body. She (Miss Lawrence) did not wonder, if they looked at the defects which the Royal Commission found. First they found that the Board was understaffed and that its duties entailed much travelling over the country. The Government proposed to remedy that and to bring the Board of Control into much closer relations with the Ministry of Health than ever it had been before. It would be more in the position of a Department of the Ministry. The Chairman to be appointed by the Ministry of Health was to be an executive officer—that was to say, in the position of head of a department, and the House need not be afraid that there would be no Parliamentary control.

The Bill was read a second time.

THE SECOND READING OF THE BILL.

On the motion for the second reading of the Mental Treatment Bill in the House of Commons on Feb. 17th,

Borderline Cases

Dr. VERNON DAVIES said he felt that the Bill was of so much importance that the House was entitled to consider it further on one or two points which so far had not been mentioned. It was not a lunacy Bill; it was not a mental defective Bill. It was a Bill to get at the unfortunate cases before lunacy and certification were reached. That brought forward a most important point which had not been sufficiently stressed, and that was the case of the voluntary boarder or voluntary patient. One of the most tragic events in any family was the suspicion that one member might be mentally unbalanced; on the top of that was the fear that this might lead to insanity; and after that, if the case unfortunately did become insane and the patient was certified, there was the horror and shame and the stigma which remained upon the whole family. In the case of adolescent children it might very well affect their future life. The result was that in all classes of life families had done all they could to hide these cases. On the earliest suspicious sign of mental instability they went to their doctor. One of the most tragic things that could happen to any man in private practice—it had often happened to him—was when a poor patient, perhaps a woman, worried to death and with little money, her husband out of work, found that she could not sleep, that her nerves gave way, and she asked "Oh, doctor, am I going mad?" Then there was the ex-Service man who had been struggling against adversity, and fighting against overwhelming odds, until he overbalanced for lack of treatment. There was also the business man who under the stress of modern life worried until he reached the point where he broke down, and they had records of suicides and other troubles. Would it not be better if it could be arranged that these people should know that treatment, absolutely separate and distinct from any suggestion of insanity, was available for them? If a man had an illness of the lungs he went to a doctor or to a hospital, had his ailments diagnosed and underwent the appropriate treatment. But once the word "mental" was mentioned a patient became worried, and what they needed was a change in the public idea towards mental illness. It should be regarded just as physical illness was regarded, and the public should get the idea that it could be treated with the hope of effecting an improvement. The House of Commons had a great opportunity. The Minister of Health had been even braver than the Royal Commission. The report of the Commission marked a distinct advance, and the Minister had advanced a little beyond that report. He (Dr. Davies) would like to see the House advancing a little beyond the Minister. Let them take their courage in their hands and say that they were determined to recognise mental illness in the same way as physical illness and not as insanity. The Bill fell short of carrying out that idea. The Bill said that the voluntary patient might be received after he had given notice, or in the cases of an infant after notice had been given on his behalf, and the case was then to be notified to the Board of Control. That spoiled the whole scheme. He had nothing against the Board of Control, but in the eyes of the public the Board of Control meant the case was one of lunacy. Suspicion would be aroused, and among working people and uneducated people there would be no voluntary patients at all on account of the stigma and the fear of lunacy. The Minister ought to be courageous and advise the House and the country to treat the voluntary boarders as patients suffering from a physical illness pure and simple. In no circumstances should they be notified to the Board of Control, unless special arrangements were found necessary in the case of infants sent in by parents or guardians. By this means they would induce the people they wanted to get at to submit to treatment.

"Temporary" Cases.

When they came to the other cases the great danger was going to be that every case in the future that was not a voluntary boarder would be called a temporary case, because no doctor would commit himself to saying that a patient could not get better in six or twelve months. Prognosis in mental disease was not easy, and no doctor, for his own sake, would say "I will certify this case as a lunatic, and there is no chance of recovery." The doctor would hope that the cases would improve within the six or twelve months and would put off the stigma of certification as long as they could. There was no reason why they should not do that, and he thought that Sir Boyd Merriman had looked at the matter too much from the legal aspect. He (Dr. Davies) thought that the Board of Control was the only safeguard for patients, because they were an independent body of medical and legal men, with some others, having expert knowledge of administration and lunacy or mental work, absolutely unrelated to any of the local authorities, and having the interest of the patient at heart. They wanted to see first of all that the patient was in proper circumstances, in a proper building, and that he was properly treated; and they had the power of compelling the patient either to be discharged as cured or certified if necessary. They were absolutely independent of all parties, except the Minister of Health. It was practically an impossibility for any patient to-day to be improperly detained. He would increase the powers of the Board of Control, and would make them responsible to the House of Commons, but he would not in any circumstances allow them to have anything to do with voluntary boarders. One of the great defects of the Bill was that voluntary boarders might go to mental hospitals—that was to asylums. That was absolutely ridiculous and fatal. Borderline nervous cases would go into mental hospitals and mix with real cases of insanity, and that would be just the sort of thing to topple the former cases over the line. These cases should be sent as out-patients to other hospitals. There were three hospitals that had these patients, one at Cardiff, one at Oxford, and the Middlesex Hospital in London. The Bill gave the power to extend that. He felt strongly about this Bill, because they were at the parting of the ways. This was going to be an epoch-making measure, and he wanted the Minister of Health to have the credit of it, because he had had the courage to go a little beyond the report of the Royal Commission. He wanted the House to have the courage to go even beyond the Minister in the direction which he had indicated.

Are Safeguards Safe?

The safety of safeguards for the medical profession had been raised. The safeguards in the Bill were absolutely valueless, because he would be a very poor lawyer who could not make out a prima facie case to satisfy any judge, and he did not think the remedy of Sir Boyd Merriman was very much better. He recognised that it was a defficult thing to deal with, but he asked the House to bear in mind that the medical profession was an honourable profession. They really tried to do the best they could for their patients, and they had no desire to see people locked up or certified as insane when they were not insane. Doctors at the present time, owing to the difficulties which had arisen, refused to certify cases, and they would find that doctors would refuse to recommend under this Bill. There was a simple way out of the difficulty. Why should not the Board of Control when they came across a case where a certification was wrong, as where it was alleged that a medical man had betrayed the trust reposed in him, and had kept under control a patient who ought not to have been kept under control, refer the facts to the General Medical Council? If the Council said "we believe the charge to be true" and struck the doctor's name off the roll, that action would *ipso facto* be evidence in support of any proceedings taken against him to recover damages. By these means they would get out of all legal quibbling.

THE BILL IN COMMITTEE.

A Financial Resolution.

The second reading of the Bill having been agreed to without a division, the House proceeded in committee to discuss the following financial resolution in connexion with the measure:—

> "That, for the purposes of any Act of the present Session to amend the Lunacy Acts, 1890 to 1922, and such of the provisions of the Mental Deficiency Acts, 1913 to 1927, as relate to the constitution and organisation of the work of the Board of Control, the exercise of the powers of the Board and the protection of persons putting those Acts into operation, it is expedient to authorise the payment out of moneys provided by Parliament—(*a*) of such salaries as may be fixed by the Minister of Health with the consent of the Treasury to the chairman of the Board of Control and to such number of senior commissioners, commissioners other than senior commissioners, and assistant commissioners as may be fixed; and (*b*) of such annual superannuation allowances, additional allowances, and gratuities under the Superannuation Acts, 1834 to 1919, as may, by virtue of the said Act, become payable to persons who, being persons in the service of a local authority in respect of whom contributions have been paid under the Asylums Officers' Superannuation Act, 1909, are appointed to be commissioners or assistant commissioners, or to the legal personal representatives of such persons."

The Board of Control.

Sir **Kingsley Wood** said if they passed the resolution they gave authority, subject to any alterations which might be made in committee, for a reconstitution of the Board of Control. The Board had responsible and important duties. The criticisms levelled at the Board had not been in regard to personnel, or the manner in which they were carrying out their duties, but that there were not a sufficient number of commissioners, and that the staff was inadequate. Most members of the House recognised that the difficult and delicate work of the Board had been carried out satisfactorily, and that statement was borne out by the report of the Royal Commission. His (Sir Kingsley Wood's) criticism was not directed in any way at the Board of Control, but rather to examine before they authorised the payment of these salaries under the new constitution, whether they would improve the Board by the suggestions in the financial resolution and in the Bill. He would like to know what justification there was for the division between senior and junior commissioners? In the present Board of Control the members were equal in status, and were recognised as full members. Would it detract in any way from the position and influence of the Board to make this division? The commissioners would have to visit many important institutions, and Parliament should give them all possible authority in order that they might carry out their work. He also wanted to know whether the Minister of Health would see that there were enough commissioners for that purpose. Did the right hon. gentleman contemplate a lay representative and a woman on the Board? Dealing with superannuation, Sir Kingsley Wood said that he understood that in the case of an officer who was now a servant of a local authority and was appointed one of the assistant commissioners, the years of service he had had with the local authority would count for pension as if his services had been rendered the whole of the time under the State. He would like to have confirmation of that from the Minister of Health.

The Minister's View.

Mr. GREENWOOD (Minister of Health) said that it was clear that the present organisation of the Board of Control was not such as might ensure effective administration. It was difficult to have a body—a soviet of people—all co-equal who were engaged on the business of visitation in the country and central administration at headquarters. It was clear that to get effective administration on the lines laid down in all other departments they should differentiate between those who had final responsibility and those who were concerned with visitation and inspection. The distinction made in the Bill between senior commissioners and other commissioners, including the assistant commissioners, was made in order that they could get this clear demarcation—the senior commissioners would be primarily engaged on central administration, control, and policy; the other commissioners would be primarily engaged in the work of visitation and inspection in the provinces. That was according to sound methods of administration. Provision would be made that at least one commissioner should be a medical commissioner, and that at least one should be a woman. The intention at present was that there should be two medical commissioners, one legal commissioner, and one woman. The Chairman in addition to the four would not be lay in the sense of being neither legal nor medical, because after all they were being called upon to undertake responsible executive and administrative duties, some of which were legal and some medical in their character. These people must be experts; they were going to be the senior officers of this branch of the public service. The question of the commissioners' salaries, emoluments, and pensions was one for discussion and agreement with the Treasury, and such discussions were going on at the present time. As was laid down in the Financial Memorandum, it was not anticipated that the additional cost from the development in contemplation would be more than £6000 a year. Quite clearly people who were to have such heavy responsibilites with regard to mental disease as the Board of Control must be people who had considerable knowledge of this question, and as vacancies occurred it might be desirable to reinforce the staff from people who were engaged in the mental hospital service. But it was difficult to attract these people into the service, because, as the law stood now, they lost their superannuation rights, and because cases might occur where men would not serve a sufficient number of years—the necessary minimum was ten years—to qualify for the pension he would have got had he continued in the local government service. The arrangements under Clause 11 of the Bill were designed to get over that difficulty by spreading the burden of superannuation over the Board of Control service and the service of those public authorities under which the commissioner had served in the mental hospital service.

After further debate the financial resolution was agreed to.

On the following day, Feb. 18th, the resolution was agreed to by the House on report.

Power to Receive Voluntary Boarders.

The Mental Treatment Bill was considered by Standing Committee A of the House of Commons on Tuesday, Feb. 25th. Mr. CECIL WILSON was in the chair.

On Clause 1 (Power to Receive Voluntary Boarders)

Dr. VERNON DAVIES moved to leave out the words "for mental disorder," making the clause begin "any person who is desirous of voluntarily submitting himself to treatment," &c. He said that the horror of lunacy was sufficient in many cases to send patients over the border line. He hoped that they would in this part of the Bill get as far away from the idea of lunacy as possible, and endeavour to put mental illness on the same plane as physical illness. In moving all his amendments to this Bill he was acting independently, but this particular amendment was in accordance with the view of the Medico-Psychological Association. The object was entirely the good of the patient.

Mr. GREENWOOD, Minister of Health, said that if the words were left out as suggested by Dr. Davies it would appear as if the treatment was of a general character for any kind of ailment. There must be a name for mental disorder, and it must be described.

Lieut.-Colonel FREMANTLE said he was sorry that the Minister of Health took that line. He (Colonel Fremantle) wished to reinforce what Dr. Davies had said. To keep in the words "mental disorder" would definitely cut out certain of the patients who were in the early stages of mental disorder, but whose minds were perfectly clear.

Mr. RHYS DAVIES supported the amendment.

Mr. C. WILLIAMS suggested that for the word "disorder" sickness or illness should be substituted.

Dr. MORRIS-JONES said that he could not absolutely gree with Dr. Davies and Colonel Fremantle, but he went a certain way with them. He did not like the phrase "mental disorder," and he thought that "mental illness" would be better.

Mr. GREENWOOD said that if it would ease the opposition to the clause he would be prepared to substitute the word "illness" for "disorder."

Sir B. PETO said that that hardly met the case, because the treatment was to be preventive as well as curative.

Sir D. NEWTON suggested that the matter might be deferred until the next meeting of the Committee in order to allow the Minister to give it further consideration.

Mr. GRENFELL said he understood that the object of this clause was to make it possible for a person to go into an institution without implication of any kind.

Dr. DAVIES suggested to the Minister that as the word "mental" seemed to be a difficulty he might find some other word to substitute for it, such as "nervous" or "psychological."

Mr. GREENWOOD said they had to face the fact that they were dealing with mental illness. There must be a restriction. They could not alter the title of the Bill to a Bill for the treatment of psychological, nervous, or other unnamed illnesses. The terms lunacy, mental deficiency, and so on, had always been used, and they were well known. Hon. Members were applying a stigma to the term "mental," but they could not get away from the stigma, in so far as it was a stigma, by merely pretending that it had not got a name. He did not think there was anything objectionable in the phase "mental illness," because that had some similarity with other forms of illness. He was quite prepared to try to find another word for "mental" before the report stage, but he could not promise that he would be successful in doing so.

Dr. DAVIES said that he could not accept the term "mental illness," but on the understanding that Mr. Greenwood would look into the question of finding an alternative for the word "mental" before the report stage he would withdraw his amendment.

The amendment was withdrawn.

Other Amendments.

Mr. GREENWOOD then moved to substitute the word "illness" for "disorder" in the clause.

Lieut.-Colonel FREMANTLE said that he could not vote for the amendment. The word "disorder" had a wider application than "illness."

Mr. GREENWOOD said that he thought he was meeting the wishes of the Committee. He thought that Colonel FREMANTLE was alone on the Committee on this point.

Sir G. BERRY said that he was entirely at one with Colonel Fremantle. It was most unfortunate that the Minister should not realise that the real crux of the matter was the retention of the word "mental," which destroyed to his (Sir G. Berry's) mind the object for which this Bill was introduced. He suggested that some other word like "unbalanced," or something like that, should be substituted.

Mr. GREENWOOD'S amendment was agreed to.

Lieut.-Colonel FREMANTLE moved an amendment providing that the person desiring to submit himself as a voluntary boarder should make written application to the person in charge of the institution into which he wished to be received.

Mr. GREENWOOD, while expressing his willingness to accept the principle of the amendment, suggested that the words should be limited to the person in charge, as that person was specially defined in Clause 21 of the Bill.

Mr. KINLEY moved an amendment to the amendment providing that the application should be made to the medical officer of health for the area.

Dr. MORRIS-JONES said that Mr. Kinley's amendment might be possible in the future, but at present it was quite impracticable. Medical officers of health as such did not know anything about lunacy, which required a special training.

Sir BOYD MERRIMAN said he thought that for the protection of anyone in charge of an institution Colonel Fremantle's amendment was very necessary. If any question were to arise as to the liability of anyone in charge of an institution for the detention of a patient he should be able to produce a written application for admission addressed to him and signed by the patient.

Lieut.-Colonel FREMANTLE said that Mr. Kinley's proposal would not be practicable. He was grateful to the Minister for meeting him on this point, and he was quite willing to accept the shorter form which Mr. Greenwood suggested.

The original amendment, in the form suggested by Mr. Greenwood, was agreed to.

Mr. Greenwood moved a series of amendments, the object of which were to substitute the phrase "voluntary patient" for "voluntary boarder" in the Bill.

The amendments were agreed to.

The Board of Control and the Voluntary Boarder.

Dr. **VERNON DAVIES** moved the first of a series of amendments designed to secure that the Board of Control should have nothing whatever to do with the voluntary boarders taken under this Bill. He said that he was not against the Board of Control; he was in favour of the Board, and proposed to support them throughout with the exception of this one question of the voluntary boarder. Unless they could get these cases early the Bill would be a failure. They must do everything they could to encourage the people to come for treatment, but if they had to be reported to the Board of Control that would be a great barrier to public confidence, because the question of lunacy would be immediately raised. The only proviso he would make would be in respect of an infant who might be submitted for treatment by a parent or guardian. It might be necessary to see that such infants were safeguarded.

Mr. **GREENWOOD** said that he quite appreciated the point of the amendment. What Dr. Davies was trying to do was to prevent the Board of Control from having to approve every individual case of a voluntary patient to be received into single care. There was probably something to be said for that. But it would be necessary for the Board to approve the persons who made a profession of taking these patients into single care. Conditions would have to be laid down for the recognition of such persons for that purpose, and such recognition must be subject to revocation.

Dr. **DAVIES** said that so long as the Minister recognised his desire that the Board of Control should have nothing to do with the individual voluntary patients his point would be covered.

Dr. Davies's amendment was eventually withdrawn, and words suggested by Mr. Greenwood designed to carry out the same point were under discussion when the Committee rose.

COLONIAL HEALTH SERVICES.

ON Monday, Feb. 24th, the House of Commons went into Committee on a Supplementary Estimate of £4250 for salaries and expenses of the Colonial Office.

Dr. **DRUMMOND SHIELS** (Under Secretary to the Colonial Office), in the course of a statement on the

Work of the Development Fund Committee,

said that it would be agreed that the first essential to any development and substantial improvement in a colony, and to its capacity to afford employment to its own people as well as to people in this country, was that the people in the colonies should be in a proper physical condition. The Colonial Development Advisory Committee had given considerable attention to proposals which had been put before it for improving the health and conditions of the people in the colonies. The Committee had already reported favourably on more than 20 schemes from many parts of the Empire, all of which aimed at improving the health, and thereby the efficiency, of the populations. In Tanganyika Territory money was being provided in connexion with tuberculosis, which was fairly prevalent there. It was hoped that as a result of that work some increased knowledge would be gained as to how to tackle this serious scourge in Africa, and especially in East Africa. Three venereal disease clinics were being established in Swaziland. Approval had also been given for the erection in a West Indian island of a well-planned group of concrete houses to replace insanitary wooden structures. In Somaliland steps were being taken, with assistance from the Fund, to establish a supply of pure water. There were other water schemes and schemes of drainage in connexion with Freetown, Sierra Leone, which had been a very malarious port, and drainage works had been put in hand in St. Lucia and Dominica. A medical training school was being established in Tanganyika for a big, wide development of native medical assistance, which was a very much-needed development in that country. It was hoped, as a result, that a great many African dispensers and sanitary inspectors would be trained. For the inauguration of a sanitary campaign at Antigua £10,000 had been provided, and the neighbouring island of St. Kitts had received visits from highly qualified medical experts and a member of a well-known firm of sanitary inspectors. The total cost of the various projects was about £170,000, of which £112,000 was being met either by direct grants or loans from the Development Fund. He thought the House would feel that money spent in improving the public health of the colonies was money very well spent.

Medical Research and Sanitation.

Mr. **AMERY** said that he was glad that those responsible for the conduct of the Colonial Development Fund had regarded the question of health as being within its scope. Nothing in the long run could lead to greater development of trade with the various colonies than anything which strengthened the health and efficiency of the population. Therefore he welcomed the expenditure on medical research and sanitary work, and hoped that it would continue. Dr. Shiels had referred to the sanitary conditions in the West Indies, and he wished to draw his attention to the defective state of many of the hospitals there. His attention was repeatedly drawn to them when he was at the Colonial Office, but so long as they were necessarily dependent on the revenue of small impoverished colonies, it was a difficult matter to remedy. The Development Fund could step in in a case of that sort, and give assistance in a way in which it was very difficult to get from the Treasury; they would not be justified in getting it from local resources in view of the existing depression in the West Indies. If Nyassaland were to be opened up by the new connexion with the sea, it would be well worth while at the same time relaxing a little the extreme rigour which limited its medical and sanitary services. Anything that could be done to conserve the health of a very fine race of the natives in Swaziland merited attention.

Sir E. **HILTON YOUNG** congratulated the Advisory Committee on taking so wide a view of their functions, particularly as regarded the assistance they were giving to improve health conditions in the tropical colonies, and on the far-sighted and enlightened manner in which they were prepared to give the assistance of the best expert advice. There was a clear example of what one might call the unearned increment to be gained from a very small investment of public money. There were some regions on the East Coast of Africa where whole populations were depressed well below the level of vigorous production by an endemic disease called ankylostomiasis. A small investment of money would result in, as it were, pressing a trigger and shooting the population up to a higher level. One could not have a more conspicuous instance of how State expenditure could occasionally do good.

Scientific Advisory Representatives.

Mr. **ORMSBY-GORE** asked why the authorities did not employ on this Advisory Committee any representatives of modern science. Dr. Shiels had told them that grants were being made for medical research and tuberculosis work in East Africa. Those were very admirable proposals, but he (Mr. Ormsby-Gore) questioned how far the Committee, in its personnel as they had heard it, was fully qualified to decide between those projects which were of major importance and which were of minor importance. He would have felt happier if it were clearly understood that when any project dealing, say, with medical development was under consideration, either the medical adviser to the Colonial Office, the Secretary of the Medical Research Council, or the head of the London School of Tropical Medicine would be asked to join the Committee in order to give the other members of that body full advice as to what was being done elsewhere and the best line to take. Had the Committee established any principle or rule for the distribution of money? Did they, when it came to giving money to establish a particular institution, such as the new medical school at Dar-es-Salaam—if it were at Dar-es-Salaam—give, as a principle, what was called "fifty-fifty?" Did they give half the money to establish the new institution on condition that the territory locally found the other half; or was it clear to colonial Governments that if they put forward schemes for the consideration of the Committee, the Committee was prepared to give more than half the money required? He particularly rejoiced that the Committee was going into the question of health services, and he hoped that the 20 schemes before them in that connexion would only be the forerunners of many more, because he knew of hundreds of cases where some of the major requirements necessary before commercial development and ultimate trade and expansion in that country could be secured, were being held up by the ravages of tropical diseases, which were being fought gallantly by a small band of men and women. It needed the efforts of research workers in this country and out there, and needed further support, financial and otherwise, for the purpose of helping people who knew nothing of modern science [illegible] terrible death-rate and sickness which obtained in those countries with a knowledge of how to protect themselves against infection, and how to deal with [illegible] when they had got it.

Reply to the Debate.

Dr. **SHIELS** replying to the debate, said that in regard to the building of the Zambesi bridge, which was one of the biggest schemes which had been aided, the wording of the contract to ensure the proper housing and [illegible] sanitary services, and the feeding and proper medical [illegible] of all the workers engaged, was at present under negotiation and consideration. He assured Mr. Ormsby-Gore that the Committee had had the feeling that it was [illegible] expert in all services, especially in the health services. On the Committee's initiative a medical advisory Committee was now being formed, apart altogether from the Research Committee, and he thought that probably in time it would become one with the Research Committee. That Medical Committee was being formed in response to the wish of the Committee to have a broad set of principles on which they could base their medical recommendations. The preparations had gone forward, and the Medical Committee was on the eve of being set up.

The vote was agreed to.

HOUSE OF COMMONS.

Tuesday, Feb. 18th.

Oatmeal and the Decay of Teeth.

Lieut.-Colonel Fremantle asked the Secretary of State for Scotland whether his attention had been called to the report of recent investigations at Sheffield University, now being published by the Medical Research Council, which showed that oatmeal promoted the decay of teeth; and whether he would publish recommendations for remedying this danger in the Scottish national dietary.—Mr. Johnston, Under Secretary of State for Scotland, replied: I have been informed of this report which extends and amplifies previous accounts of these important investigations into the relation of diet to the proper development of the teeth. The results do not show that oatmeal and other cereals are necessarily deleterious, but that they increase the body's requirements of vitamin D. The fact of the matter is that our people had far better teeth when they were consuming more meal than they are doing to-day.

Lieut.-Colonel Fremantle: Does the hon. gentleman not realise that it is necessary to show that oatmeal by itself is very deleterious, and that it is necessary to have such things as cod-liver oil or something like that with it?

Mr. Johnston: The same statement has been made about fish, sugar, milk, and other necessaries of life.

Mr. Sanders: Will the hon. gentleman's department take care not to place too much importance upon the varying superstitions and illusions of the medical profession? (Laughter.)

Mr. Johnston: The answer is in the affirmative. (Laughter.)

Lieut.-Colonel Fremantle: Will the hon. gentleman deny the suggestion that the reports of the Medical Research Council under the Government are superstitions and illusions?

Mr. Johnston: No, Sir, but I would say they frequently contradict themselves. (Laughter.)

Miss Rathbone asked if the hon. gentleman would prepare a statement showing what proportion of the agricultural and urban workers of Scotland were in a position to pay for cod-liver oil and other articles of diet recommended?

No answer was given.

Child Malnutrition in Scotland.

Miss Lee asked the Secretary of State for Scotland the number of children suffering from malnutrition in Scottish schools; and what steps were being taken to provide for these children.—Mr. Johnston replied: The total number of children suffering from malnutrition in any year cannot be stated exactly, as complete figures are available only for the three age-groups examined each year. The numbers in these age-groups, the numbers whose nutrition was stated to be below average, the numbers whose nutrition was stated to be very poor, and the percentage ratios which the numbers in these two categories bore to the total numbers in the age-groups examined were as follows in the school years 1924-25 to 1928-29:—

Year.	Numbers in age-groups examined.	Nutrition stated to be below average.	Percentage of total examined	Nutrition stated to be very poor.	Percentage of total examined
1924–25	215,288	15,040	7·0	391	0·18
1925–26	243,595	15,990	6·2	340	0·14
1926–27	237,692	14,956	6·3	364	0·15
1927–28	249,142	16,252	6·7	359	0·14
1928–29	254,044	14,876	5·9	319	0·13

The total number of children on the school registers in 1928-29 was 814,836. If the percentages given above are applied to the whole school population the approximate numbers for 1928-29 would be:—

Nutrition below average	47,749
Nutrition very poor	1,059

The children whose nutrition is below average are not necessarily being underfed, but where it is brought to the notice of the Education Authority, by medical inspection or otherwise, that a child is, owing to lack of food, unable to take full advantage of the education provided, it is the duty of the authority to take steps to provide for the necessities of the case, or to secure that provision is made, by the procedure prescribed in section 6 of the Education (Scotland) Act, 1908. I have no reason to think that education authorities are neglectful of their statutory duty in this matter.

Use of Poisonous Gas in War.

Mr. Ayles asked the Secretary of State for Foreign Affairs whether the use of smoke screens, tear gases, and high-explosive shells producing poisonous fumes were prohibited under the Geneva Protocol (Protocol for the prohibition of the use in war of asphyxiating, poisonous, or other gases, and of bacteriological methods of warfare. Geneva, June 17th, 1925: Cmd. 3398); and, if not, what steps His Majesty's Government were prepared to take in order that the use of poison gas in any form and for every purpose of warfare might be completely proscribed.—Mr Dalton, Under Secretary for Foreign Affairs, replied: Smoke screens are not considered as poisonous, and do not therefore come within the terms of the Geneva Gas Protocol. Tear gas and shells producing poisonous fumes are, however, prohibited under the Protocol. In the circumstances no further action by His Majesty's Government is necessary.

Wednesday, Feb. 19th.

Mental Deficients and Child-bearing.

Major Glyn asked the Prime Minister whether his attention had been directed to certain public statements by His Majesty's judges regarding the consequences of mentally deficient persons bearing children, which resulted in considerable cost to the ratepayers; and whether he would consider setting up a committee to inquire into the whole matter unless this subject could forthwith be referred to an existing commission, so that legislation in accordance with their recommendations might be introduced at an early date.—Mr. Greenwood replied: The reply to the first part of the question is in the affirmative, and the subject has for some time past been under consideration. The issues involved are far-reaching and controversial; they could only be examined effectively by a suitable body specially set up for the purpose; and I fear that I cannot undertake to initiate such an investigation at the present time.

The Malaki Sect.

Mr. Horrabin asked the Under Secretary of State for the Colonies whether he had any information as to the growth in Uganda of the Christian sect known as Malakites; whether the government of Uganda had decided on any steps for the suppression of this sect; and, if so, for what reasons.—Dr. Shiels replied: The Malaki sect, so called from the name of one of its founders, made its appearance in Buganda in 1914, and made rapid progress in many parts of the Protectorate of Uganda during the first two of three years of its existence. The tenets of the sect are based on a literal and distorted interpretation of the Bible, the main plank in its platform being a strong objection to all medical, sanitary, and veterinary measures; an objection which is traceable to the fact that, in modern Luganda, the word employed to signify a medical practitioner is the same as that which, in the Luganda version of the Bible, is used to translate such words as wizard and sorcerer. The policy of the Government towards the Malaki sect from its inception has been one of non-interference, provided its adherents have not, by endangering public health or public property, transgressed against such Ordinances as those providing for the control of small-pox, plague, or rinderpest. The attitude of the members of the sect, as a whole, has been one of passive resistance to medical and veterinary activities, and it is only within the last three years, and then only in a portion of the Bulemezi country of the Mengo district, that any active opposition has been shown. As recently as March last the Governor received reports from all provinces which indicated that the Malakites were steadily decreasing both in numbers and influence. The recent incident referred to in the press was not a general movement, but the work of a few fanatics.

Medical Men in the Factory Service.

Dr. Vernon Davies asked the Home Secretary under what powers he appointed medical men to the factory service; were such medical men under lay control in his department; and, if so, whether, in view of the recommendation adopted by this country at the Washington Conference, he would constitute a separate health department for this service.—Mr. Clynes replied: The medical inspectors of factories are appointed in pursuance of the general powers conferred by Section 118 of the Factory and Workshop Act, 1901, for the appointment of such inspectors as may be necessary for the execution of the Act.

They constitute a separate, but integral, branch of the factory department, and the senior medical inspector who is in charge of the branch acts under the directions of the chief inspector of factories. The answer to the last part of the question is in the negative. As already explained to the hon. Member, in reply to his question of the 11th instant, it is understood that the intention of the Washington recommendation was to secure the establishment of a medical branch in connexion with factory inspection, and this is already given effect to in the existing arrangements.

THURSDAY, FEB. 20TH.

Miners' Nystagmus.

Mr. TINKER asked the Home Secretary, for the year 1928, the number of cases in the mining industry which had been certified as suffering from miners' nystagmus and who had been paid compensation; and the total number of old and new cases at present receiving compensation because of this disease.—Mr. CLYNES replied: The returns for 1928 show that the total number of cases in the mining industry in which compensation was paid for this disease was 9818. These were made up of 7264 old cases and 2554 new cases. I regret that no later figures are available.

Silicosis.

Mr. MARDY JONES asked the Home Secretary whether his attention had been drawn to the hardships inflicted upon the victims of silicosis and their dependents who contracted this industrial disease prior to Jan. 1st, 1929, due to the following conditions laid down in the Various Industries (Silicosis) Scheme, 1928; that no compensation was payable to any workman who contracted silicosis prior to Jan. 1st, 1929; nor where the silica rock worked upon contained less than 50 per cent. free silica; and would he undertake to antedate the operation of the Order by a year or two at least, and at the same time effect a substantial reduction below the present 50 per cent. of free silica in the rocks worked.—Mr. CLYNES replied: The only persons not covered by the Scheme are those who had ceased to be employed in the industries before Jan. 1st, 1929, and while I fully appreciate the hardship which may arise in such cases, I am advised that I should have no power under the Act to give the Scheme any such retrospective application as my hon. friend suggests. As regards the 50 per cent. limit, I would refer him to the reply I gave to a similar question on Nov. 18th last by the hon. Member for Carmarthen. No cases of hardship caused by this limitation have been brought to my notice, but if my hon. friend has any evidence to the contrary I shall be glad to consider it.

Mr. MARDY JONES asked the Home Secretary if he would state how many miners had been granted compensation under the Workmen's Compensation Acts, due to silicosis, in pursuance to the Various Industries (Silicosis) Scheme, 1928, for the year 1929, or for as many quarters of that year as the data were available, showing the total of cases for each coalfield separately.—Mr. CLYNES replied: I regret that no figures are available at present. Returns under this Scheme are collected as part of the general returns under the Workmen's Compensation Act, and as the Regulations under that Act provide only for annual returns, which are not due until March 1st, and as the tabulation necessary occupies a considerable time, I am afraid it will be several months yet before I am in a position to furnish any reliable figures for 1929.

Anthracosis.

Mr. HOPKIN asked the Home Secretary if he is now ready to appoint a departmental committee to inquire into the causes and medical history of anthracosis as it was found in the anthracite district of South Wales, with the view of placing it upon the schedule of diseases under the Workmen's Compensation Act.—Mr. CLYNES replied: I have still no evidence before me to show that the condition of the lungs described as anthracosis is a cause of disablement. The Medical Research Council, however, are setting up, at my request, an expert Committee to institute and coördinate research into pulmonary disease from silica and other dusts, and with the concurrence of the Mines Department I propose to bring the question of the effects of coal dust under the consideration of this Committee.

Treatment of Rheumatism.

Mr. THOMAS LEWIS asked the Minister of Health whether, in view of the fact that diseases classified as rheumatic were responsible for the loss of over 3,000,000 weeks of work per annum by insured workers, necessitating the payment of nearly £2,000,000 in benefit, he would consider the desirability of inaugurating a board qualified to undertake research work as supplementary to, but in conjunction with, the new British Red Cross Society clinic against rheumatism.—Mr. GREENWOOD replied: I shall watch with interest the experiment about to be made by the British Red Cross Society in the treatment of rheumatism at their new clinic, but I do not think it necessary or desirable, at this stage, to set up any special body to coöperate with the Society. The general question of research in relation to rheumatic diseases is constantly under the consideration of the medical research council, who will, no doubt, take steps to acquaint themselves with the results of the work at the new clinic.

Panel Doctors and Expensive Medicines.

Mr. SORENSEN asked the Minister of Health whether doctors were allowed to prescribe medicine for panel patients regardless of cost.—Mr. GREENWOOD replied: Insurance doctors are not only entitled, but required by their terms of service to order on the proper form any drugs or prescribed appliances which are reasonably necessary for the adequate treatment of their patients.

Psittacosis.

Mr. HACKING asked the Minister of Health whether his investigations had brought to light from what part of the world the parrots had come which have been found responsible for infecting human beings with psittacosis; whether they were the green or grey variey; and whether he could assure the public that parrots which had been in this country for a certain period of time, and had not been in contact with the disease, were immune from spreading infection.—Mr. GREENWOOD replied: I understand that the parrots associated with cases of psittacosis in this country have been mostly green parrots imported from South America. As regards the last part of the question, I am not in a position to give any definite assurance, but I am advised that the risk of contracting the disease from a parrot which has been in this country for some months, and has not been in contact with infected birds, may be regarded as negligible.

Local Authorities and Birth Control Information.

Mr. SIMON asked the Minister of Health under what Statute local authorities were prohibited from giving information regarding birth control to nursing mothers, attending maternity and child welfare centres, who needed this advice on medical grounds.—Mr. GREENWOOD replied: I am not aware of any such Statute.

Slum Clearance Schemes.

Miss RATHBONE asked the Minister of Health whether he would so expedite the making up of accounts relevant to the cost of slum clearance schemes under the Housing Act, 1923, that the House might have, at least, approximate figures showing the average expenditure per dwelling incurred out of public funds in, at least, some of the schemes carried out under existing legislation before it was asked to embark on a new policy of slum clearance under the promised new Bill.—Mr. GREENWOOD replied: Although, as I have informed the hon. Member, figures of average annual loss on slum clearance schemes have not in any case been fixed, the final accounts showing the capital cost of several of the completed schemes have been made up, and estimates have been made of the probable average annual loss on the basis of present rents and on certain assumptions as to the selling price of the cleared sites. These estimates show, as regards ten completed schemes under the Housing Act, 1923, for which accounts have been received, an annual loss of about £2 per person displaced from slum areas.

Analysis of Imported Preserved Milk.

Mr. OSWALD LEWIS asked the Minister of Health whether the Government chemist was satisfied, as a result of analyses made by his own department within the past 12 months, that all the forms of preserved milk which were at present being imported into this country in any considerable quantity were nutritious, and that they did not contain anything likely to render them harmful as an article of diet.—Mr. GREENWOOD replied: From the reports of the Government chemist on the samples of imported preserved milk analysed by his department within the past 12 months, I am satisfied that all the milks examined were nutritious, and that they did not contain anything likely to render them harmful as an article of diet.

MONDAY, FEB. 24TH.

Age of Marriage in India.

Mr. SORENSEN asked the Secretary of State for India what was the present minimum age for marriage in India; and whether he was aware of any protests by Indian natives against the recent law relating thereto.—Mr. WEDGWOOD BENN replied: The recent Act, which comes into operation on April 1st next, penalises the contracting, performance, or promotion of a marriage if the husband is less than 18 years of age, or the wife less than 14. Protests against the Act have been made.

Women's Medical Service in India.

Major GRAHAM POLE asked the Secretary of State for India whether an annual contribution was made by the Government of India to the Women's Medical Service for India; and, if so, whether he would state the amount of this grant, and the manner in which it was administered.—Mr. WEDGWOOD BENN replied: An annual grant of Rs.3,70,000 is made by the Government of India to the National Association for Supplying Medical Aid to the Women of India, towards the cost of the Women's Medical Service. The grant is administered by the Council of the Association.

The League and Illicit Drug Traffic.

Lieut.-Colonel FREMANTLE asked the Home Secretary whether, as a result of revelations recently made before the League of Nations Advisory Committee on Opium, he was taking any steps to secure coördinated legislation and closer coöperation between the different countries concerned in the illicit manufacture and distribution of dangerous drugs.—Mr. SHORT, Under Secretary to the Home Office, replied: The Home Office has, for a long time past, done everything in its power to promote coöperation in the enforcement of the international conventions relating to dangerous drugs, and in the suppression of the illicit traffic. As the hon. and gallant Member will be aware, the League's Advisory Committee, on which His Majesty's Government is represented, has given constant attention to this question, and as a result of the recommendations which they have drawn up very great progress in the direction of coördinated action and closer coöperation has been made. The discoveries referred to in the question were, in fact, made as a result of the coöperation between the authorities of several countries. I understand that the Advisory Committee, in the report which it has submitted to the Council of the League on the proceedings at its recent meeting, has made further recommendations on the subject, and these will receive the careful and sympathetic consideration of His Majesty's Government.

Sale of Stale Fish.

Mr. ARTHUR MICHAEL SAMUEL asked the Minister of Agriculture whether he would frame regulations of a kind calculated to discourage the sale of stale fish for curing or smoking or for consumption in fried fish shops, and thereby induce the fishing industry to observe more cleanly methods of packing and storage at sea so as to avoid fish being landed in a stale condition.—Mr. BUXTON replied: Adequate safeguards against the exposure for sale of fish intended for the food of man, but unfit for human consumption, already exist by virtue of the Public Health Acts, under which such fish may be condemned and the owner or person in possession may be fined or imprisoned. As stated in the report on the Handling and Storage of white fish at sea, which the hon. Member presumably has in mind, the term "stale" is used in a comparative sense, and does not denote that the fish is unfit for human food.

TUESDAY, FEB. 25TH.

Stamp Duty on Patent Medicines.

Mr. LONGBOTTOM asked the Secretary to the Treasury if he was aware that bottles of phosferine were being sold by grocers at 1*s.* 3*d.* each, upon which a revenue stamp of 3*d.* had been affixed, and that similar bottles were being retailed by chemists at 1*s.* 3*d.* each without revenue stamp; and, if so, what was the explanation.—Mr. PETHICK-LAWRENCE replied: The prices of medicines are not subject to official control. A regards the revenue stamp, the law exempts medicines from medicine stamp duty under certain conditions when they are sold by qualified chemists, but not by grocers.

Mr. LONGBOTTOM asked if the hon. gentleman was aware that this was the first of a series of evasions of the stamp duty for patent medicines, and whether, as manufacturers of patent medicines were pocketing the money that hitherto they had paid for stamp duty, he would consider the possibility of introducing legislation in the interest of the national revenue, to stop this wholesale profiteering.

Mr. PETHICK-LAWRENCE said that all this arose out of recent legislation, and if it should be proved that there was evasion, no doubt the matter would be considered.

Mr. LONGBOTTOM asked if the hon. gentleman knew that the wholesale price of phosferine was 13*s.* per dozen, and that the stamp duty on its sale by grocers should be 6*d.* instead of 3*d.*

Sir G. HAMILTON asked if the hon. gentleman knew the price charged by the Co-operative Societies.

Mr. PETHICK-LAWRENCE said he had no information on that point.

Consumption of "Red Biddy" in Scotland.

Mr. McELWEE asked the Secretary of State for Scotland whether he could report to the House the result of his promised examination into the injurious effects of the alcoholic beverage known as "red biddy"; and whether he had any evidence to show that this intoxicant was produced in any substantial degree in Leith.—Mr. ADAMSON replied: The inquiries which I have so far made indicate that there is a considerable sale of cheap red wines in Scotland, and that the term "red biddy" is sometimes applied to such cheap red wine, and sometimes to a mixture of the wine and methylated or other spirits. There is no evidence of the manufacture or sale in Scotland of beverages containing such mixtures, but there is reason to believe that these mixtures are made by some purchasers of cheap red wine. The effects of such mixtures are most harmful. I am informed that a considerable quantity of red wine is manufactured in Leith. I am awaiting medical reports on the subject

Milk Tests in Scottish Schools.

Mr. HURD asked the Secretary of State for Scotland how many children in how many schools would be included in the liquid milk tests in Scottish schools; and what experience of the nutritive value of liquid milk food had led to this educational experiment.—Mr. ADAMSON replied: A total of 20,000 children in 68 schools of the Lanarkshire Education Authority will be included in the present investigation into the value of an additional daily ration of milk in the dietary of the school child. Of these children, 10,000 will receive milk and 10,000 will receive no ration, but will be weighed and measured for comparison. The present investigation follows the two years' investigation on a small scale conducted in 1926–1928, and reported in the annual report of the Scottish Board of Health for 1928. The results of that investigation showed that the addition of milk to the diet produced a marked improvement in the physical condition of children of all school ages, and justifies an investigation on a scale sufficiently large to give conclusive results.

Miners' Nystagmus.

Mr. SHIELD asked the Secretary for Mines the number of miners in the coal-mines of Great Britain certified to be suffering from miners' nystagmus for the years 1923, 1924, 1925, 1927, 1928, and 1929; and in which coalfield in the country nystagmus was most prevalent.—Mr. B. TURNER replied: In 1928, the last year for which information is as yet available, the incidence of new cases of nystagmus, in proportion to the number of miners employed, was greatest in Ayrshire. Following are the figures:—

Year.	Cases continued from previous year.	Cases in which first payment was made during year.
1923	7270	3872
1924	7635	3271
1925	7890	3444
1927	7933	1801
1928	7264	2554

Boarding Out of Mental Deficients and Lunatics.

Major GLYN asked the Minister of Health how far negotiations had gone with the appropriate authorities for the accommodation and maintenance of mentally deficient persons and lunatics in cottage homes in rural areas; and if he would give an assurance that nothing of this kind would be done until an opportunity had been given for a discussion in the House?—Mr. GREENWOOD replied: Local authorities already have power to board out mental defectives and persons of unsound mind. Mental defectives have been boarded out with their guardians since the Mental Deficiency Act, 1913, came into operation, and no change of practice as regards defectives is contemplated. The boarding out by visiting committees of persons of unsound mind is provided for under Section 57 of the Lunacy Act, 1890. For various reasons it has not been possible to make much use of this provision; and the only question under consideration is whether greater use could be made of the existing powers, in view of the experience of the system in Scotland and in France.

Maternal Mortality.

Sir HERBERT SAMUEL asked the Minister of Health when it was anticipated that the departmental committee on Maternal Mortality would present its report; and whether the Government contemplated any action for the establishment of a national maternity service?—Mr. GREENWOOD replied: I understand that I may expect an interim report from this Committee during the next few weeks. As regards the last part of the question, this matter is still under consideration, and I am not in a position to make a statement on the subject.

Government and Washington Convention.

Sir WILLIAM BRASS asked the Prime Minister whether it was the intention of the Government to ratify the Washington Convention without reservations?—Miss BONDFIELD, Minister of Labour, replied: Yes, Sir.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdr. W. A. Jolliffe to be Surg. Comdr.

A. J. A. Gray to be Surg. Lt.

ROYAL NAVAL VOLUNTEER RESERVE.

Prob. Surg. Lt. R. M. B. Lowis to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. and Bt. Col. J. S. Bostock to be temp. Col.

Majs. to be temp. Lt.-Cols.: Bt. Lt.-Col. E. T. Potts, G. W. W. Ware, C. J. Wyatt, C. F. White, F. C. Sampson, and T. S. Blackwell.

Temp. Lt.-Cols. to be Lt.-Cols.: Bt. Lt.-Col. E. T. Potts, vice Lt.-Col. J. G. Bell, to ret. pay.

G. W. W. Ware, vice Lt.-Col. R. C. Wilson, to ret. pay.

C. J. Wyatt, vice Lt.-Col. H. St. M. Carter, to half-pay.

Capt. J. R. Williams, Dental Surg., relinquishes his commn.

Lt. on prob. H. C. Benson is restd. to the estabt.

To be Lts. on prob.: R. L. Whittaker, W. J. Officer, J. Beggs, N. H. Lindsay, and is secd. under the provisions of Art. 205, Royal Warrant for Pay and Promotion; T. N. Fogerty.

TERRITORIAL ARMY.

Col. F. G. Proudfoot retires on completion of tenure of appt. and retains his rank, with permission to wear the prescribed uniform.

Col. D. Rorie (ret. T.A.), to be Hon. Col., R.A.M.C. Units, 51st (Highland) Div.

Lt.-Col. (Bt. Col.) H. F. Humphreys, from Gen. List, R.A.M.C., to be Col., and to be A.D.M.S., 48th (S. Midland) Div.

Maj. A. R. Barlas, R.A.M.C., to be Divl. Adjt., 54th (E. Anglian) Div., T.A.

Maj. G. G. Drummond, R.A.M.C., to be Divl. Adjt., 43rd (Wessex) Div., T.A., vice Maj. A. J. Bado, R.A.M.C., who has vacated the appt.

Capt. C. A. Hutchinson, R.A.M.C., to be Divl. Adjt., 52nd (Lowland) Div., T.A.

Capt. W. H. Kerr to be Maj.

Lt. J. Rannie to be Capt.

Lts. F. J. L. Lang and J. G. Morgan to be Capts.

ROYAL AIR FORCE.

Flying Officer C. C. Fenton resigns his short service commission.

INDIAN MEDICAL SERVICE.

Maj. A. N. Palit to be Lt.-Col.

Capt. B. N. Khan and Lt. P. Nath relinquish their temp. commns.

COLONIAL MEDICAL SERVICES.

The following appointments have been made:—Dr. R. G. Spink, Dr. B. A. Taylor, and Dr. E. D. B. Wolfe, Medical Officers, Malayan Medical Service; Dr. D. R. Griffith, Medical Officer, Prince of Wales School and College, Achimota, and Dr. D. E. Stewart, Lady Medical Officer, Gold Coast; Dr. J. D. Robertson, Medical Officer, Kenya; Dr. R. Shelley, Medical Officer, Straits Settlements; and Dr. E. Burton and Dr. D. Murray, Medical Officers, Uganda.

Dr. A. Gaston has been appointed Medical Officer, Nigeria, West African Medical Staff.

Resignation of an Honorary Medical Staff.—The governors and trustees of the Spalding Johnson Hospital recently decided, by a small majority, to alter the rule which required that all members of the honorary medical staff must reside in the town. Outside parishes at some distance away asked for this alteration that they might be treated in hospital by their own medical attendants. Immediately the resolution had been passed the honorary medical staff—Drs. J. H. Power, W. R. Burton, S. H. Perry, and J. R. Munro—handed in their resignations.

A Neurological Unit at Manchester.—In 1926 a small experimental department of neurological surgery was established at Manchester Royal Infirmary, and the results are such as to assure the board of management that there is a demand for full facilities for the treatment of neurological affections. It has therefore been decided to adapt a block of 15 beds and to equip it with an operating theatre and the necessary adjuncts. The cost will be not less than £10,000, and it is claimed that this will be the only unit devoted to the subject in any general hospital in this country.

Medical News.

University of Cambridge.—On Feb. 21st the following degrees were conferred:—

M.D.—N. E. Chadwick and J. A. Struthers.

M.B. & B.Chir.—J. F. V. Lart and T. R. Stevens.

M.B.—J. H. L. Easton.

B.Chir.—Benjamin Wright.

Society of Apothecaries of London.—At recent examinations the following candidates were successful:—

Surgery.—T. Chandrasekharan, Madras and Manchester; B. T. W. Harvey, London Hosp.; C. B. Jennings, Charing Cross Hosp.; T. Singh, Punjab and Charing Cross Hosp.; P. Somasunder, London Hosp.; A. L. Thomas, Guy's Hosp.; and H. Whitby, London and St. Mary's Hosp.

Medicine.—B. T. W. Harvey, London Hosp.; W. A. R. Mailer, St. Bart.'s Hosp.; I. W. H. Mansfield, Middlesex Hosp.; J. E. Moody, St. Mary's Hosp.; S. Ramadas, St. George's Hosp.; and D. Ram Annamalai, London Hosp.

Forensic Medicine.—M. Asaad, St. Mary's Hosp.; L. Banszky, Middlesex Hosp.; K. W. Bruce, Durham; G. P. Charles, Westminster Hosp.; L. P. Clarke, St. George's Hosp; V. J. H. Coidan, Beyrouth and Paris; H. W. E. Dickey, Manchester; I. F. W. Edwards, and A. R. Madden, St. Mary's Hosp.; W. A. R. Mailer, St. Bart.'s Hosp.; I. W. H. Mansfield, Middlesex Hosp.; E. G. Nair, Madras and Manchester; C. Skinner, Guy's Hosp.; and P. Wade, Liverpool.

Midwifery.—R. P. Davies, Cardiff and London Hosp.; R. Frankling, Guy's Hosp.; B. T. W. Harvey, London Hosp.; C. B. Jennings, Charing Cross Hosp.; N. I. Kronengberg, Guy's Hosp.; F. G. Leekam, St. Mary's Hosp.; M. Naylor, Sheffield; D. M. Nightingale, King's College Hosp.; L. Sachs, St. Mary's Hosp.; and P. Wade, Liverpool.

The Diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery:—D. Ram Annamalai, C. B. Jennings, J. E. Moody, W. A. R. Mailer, I. W. H. Mansfield, M. Naylor, P. Somasunder, S. Ramadas, and H. Whitby.

Post-graduate Course on Mental Deficiency.—The Extension Department of the University of London, in coöperation with the Central Association for Mental Welfare, has arranged a course of lectures, supplemented by clinical instruction, on Mental Deficiency and Conditions Closely Allied to It. It will be in two parts, the first from May 5th to 10th, and the second from the 12th to the 17th. Particulars may be had from Miss Evelyn Fox, c/o the University Extension Department, Imperial Institute-road, London, S.W. 7.

Royal Society: *Smithson Research Fellowship* Our advertisement columns contain particulars of this Fellowship, which is offered for research in natural science, preferably at the University of Cambridge, during a period of four years or more. The stipend is at the rate of £800 a year, with a possibility of increase, and the object of the founder is to encourage the discovery of new laws and principles "rather than the exploitation of what is known."

Maternity and Child Welfare.—A national conference on this subject will be held at Friends House, Euston-road, London, N.W., from July 1st to 3rd, with visits to institutions on the following day. Particulars may be had from Miss J. Halford, at 117, Piccadilly, W. 1.

London School of Hygiene and Tropical Medicine.—The Minister of Health has appointed Sir Harry Goschen to be a member of the Board of Management of this School, in the place of Lord Melchett, whose term of office recently expired. The Board has elected Sir Harry Goschen as its Chairman in succession to Lord Melchett.

People's League of Health.—Twelve lectures on health will be given at 6 P.M. on Mondays, from March 3rd to May 26th (except April 21st), at Hamilton House, Mabledon Place, London, W.C. The lecturers will be Prof. H. E. Roaf, Sir Robert Armstrong-Jones, Prof. M. S. Pembrey, Mr. George Thomson, Mr. A. F. MacCallan, Prof. W. E. Dixon, Miss Margaret Hume, Dr. G. P. Crowden, Dr. C. C. Worster-Drought, Dr. I. Feldman, and Prof. E. L. Collis. The League's address is 12, Stratford Place, W. 1.

Convalescent Home for Middlesex Children.—The administrative committee of the Middlesex King Edward VII. Memorial Fund have decided to purchase Collington Manor, Bexhill, for use as a convalescent and holiday home for necessitous Middlesex children.

University of Manchester.—Dr. W. H. Lang, F.R.S., Barker Professor of Cryptogamic Botany, has been appointed a Pro-Vice-Chancellor in succession to Dr. J. S. B. Stopford, F.R.S., Professor of Anatomy.

Royal Alexandra Hospital.—At this hospital for sick children in Brighton, on Feb. 21st, a gymnasium for orthopædic work was opened by Miss Bower, on behalf of the donors, Mr. and Mrs. H. E. Bower. The roof will be used as a sun balcony for the patients in the isolation wards.

A Youthful Hospital President.—The Marquess Townshend, aged 13, has been elected President of the Eastern Counties Convalescent Home at Yarmouth, in succession to the late Dean of Norwich.

Paying Patients at Glasgow.—A paying patients' block is being erected in connexion with the Victoria Infirmary, Glasgow, and will be ready for occupation in the autumn. It has been decided to charge an inclusive fee to all patients, irrespective of the nature of the case, of £6 6*s.* per week for the first three weeks and thereafter £3 3*s.* until the completion of treatment.

Manchester Accidents.—Every day the Manchester hospitals deal with over 200 accident cases, and more than 80 operations are performed.

A "Trade Ward."—The dressmaking industry has undertaken to endow a ward of 25 beds in the Middlesex Hospital. A committee of prominent members of the trade is raising the £25,000 which the endowment will cost by means of collections among employees, dances, and other entertainments.

Hospitals and Motor Accidents.—Early last year boxes were placed in the office of the Belfast Licensing Department in the hope that motorists when renewing their licences would give a small contribution towards the cost of treating motor accidents in the local hospitals. But although there are about 15,000 drivers in the city area, the total amount contributed was less than £30.

Belfast Maternity Hospital.—The erection of a new maternity hospital of 100 beds, at a cost of £110,000, is about to be begun; it is hoped that there will eventually be a paying unit of 50 beds. Belfast's accommodation for maternity and infant welfare work is described as "about the most inadequate" in the United Kingdom. Of the money required £80,000 is already in hand.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, March 4th.—8 p.m., Pathology. Laboratory Meeting at the Medical College, London Hospital, E. Demonstrations: B. C. J. G. Knight: Technique of Eh Measurements. S. P. Bedson and G. Western: Psittacosis. F. C. Smith: A Bacterial Porphyrin. J. O. W. Bland: Generalised Vaccinia in the Guinea-pig. T. Lumsden: Spontaneous Mouse Tumours H. Cairns and Dorothy S. Russell: The Importance of Examining the Spinal Cord in all Cases of Intracranial Neoplasms. Donald Hunter and Hubert M. Turnbull: Resorption of Skeletal Calcium in Parathyroid Adenomata and Graves's Disease. W. W. Woods: Sacro-coccygeal Chordoma. Ectopic Pancreas in Gall-bladder. A. B. Bratton: Pneumonia in a Case of Psittacosis. Pyogenic Aneurysm of Aorta. 8.30 p.m., Orthopædics. Discussion on Spasmodic Flat Foot. Opener: Mr. S. A. S. Malkin. Followed by Mr. Naughton Dunn and Mr. E. P. Brockman. Other speakers will also take part.

Wednesday.—5 p.m., History of Medicine: Surgery. 8.30 p.m., Pathological Evening.

Thursday.—8 p.m., Tropical Diseases.

Friday.—10.30 a.m., Otology. (Cases at 9.30 a.m.) Discussion on Malignant Disease of the Ear. Papers by Mr. G. J. Jenkins, Dr. J. S. Fraser, and Mr. E. Broughton Barnes. Cases and Specimens: Cases will be shown by Sir James Dundas-Grant and Mr. F. C. Ormerod. 5 p.m., Laryngology (Cases at 4 p.m.). Cases will be shown by Mr. Simpson, Dr. Dan McKenzie, Mr. E. Watson-Williams, Mr. M. Vlasto, and others. 8.30 p.m., Anæsthetics. Papers: Dr. Charles Donald: Spinal Analgesia with Spinocain. Dr. Howard Jones: Percain 'Ciba,' a New Regional and Spinal Analgesic, with Special Reference to High Thoracic Nerve-root (Splanchnic) Block.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, W.

Wednesday, March 5th.—9 p.m., Sir John Thomson-Walker: Enlarged Prostate and Prostatectomy. (Third Lettsomian Lecture.)

HUNTERIAN SOCIETY.

Monday, March 3rd.—(at the Mansion House, London), Dr. J. Campbell McClure: Psychology and the Practice of Medicine. (Hunterian Oration.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

Tuesday, Mar. 4th.—5 p.m., Dr. J. A. Glover: The Incidence of Rheumatic Diseases. (Second Milroy Lecture.)

Thursday.—5 p.m., Dr. J. A. Glover: Last Milroy Lecture.

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn-fields, W.C.

Monday, March 3rd.—5 p.m.: Mr. C. E. Shattock: On Affections of Lymphatic Glands (Museum Demonstration).

Friday.—2.45 p.m.: Mr. T. B. Layton: Rhinological Anatomy of Naso-frontal Duct and Hiatus Semilunaris.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, Mar. 3rd, to Saturday, Mar. 8th.—Medical Society Lecture Room, 11, Chandos-street, Cavendish-square, W. Tues., 4 p.m., lecture by Prof. Francis R. Fraser on The Uses and Abuses of Digitalis. No fee.—Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C. Tues., 9 a.m., Special Demonstration by Mr. Nicol Rankin: Guillotine Enucleation of Tonsils in Children.—No fee.—Royal Waterloo Hospital, Waterloo-road, S.E.—Thurs., 2.30 p.m., Demonstration on Clinical Laboratory Findings by Dr. F. A. Knott. No fee.—Children's Clinical and Other Hospitals. Post-graduate Course in Diseases of Children occupying afternoons and some mornings. Second week.—Royal Eye Hospital, St. George's Circus, S.E. Series of Demonstrations on the Diagnosis and Treatment of Diseases of the Eye. Mon. to Fri. afternoons daily.—St. John's Hospital, Leicester-square, W.C. Special Course in Dermatology. Clinical instruction daily and lectures on Tues. and Thurs. afternoon.—Hospital for Tropical Diseases, Gordon-street, W.C. Clinical demonstration Tues. and Thurs. afternoons at 2 p.m.—Further particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, Mar. 3rd.—2.30 to 5 p.m.: Medical, Surgical, and Gynæcological Clinics. Operations.

Tuesday.—2.30 to 5 p.m.: Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

Wednesday.—2.30 to 5 p.m.: Medical, Skin, and Eye Clinics. Operations.

Thursday.—11.30 a.m.: Dental Clinics. 2.30 to 5 p.m.: Medical, Surgical, Nose, Throat, and Ear Clinics. Operations.

Friday.—10.30 a.m.: Throat, Nose and Ear Clinics. 2.30 to 5 p.m.: Surgical, Medical, and Children's Diseases Clinics. Operations.

KING'S COLLEGE HOSPITAL, LISTERIAN SOCIETY.

Monday, Mar. 3rd.—8.15 p.m., Prof. D. P. D. Wilkie of Edinburgh: Carcinoma of the Rectum and its Treatment.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark Hill, S.E.

Thursday, Mar. 6th.—9 p.m., Mr. A. C. Palmer: Uterine Hæmorrhage.

ROYAL NORTHERN HOSPITAL, Holloway.

Wednesday, Mar. 5th.—3.15 p.m. (at the Royal Chest Hospital), Dr. Barly King: Demonstration of Cases in the Wards.

UNIVERSITY COLLEGE, Gower-street, W.C.

Thursday, Mar. 6th, and Friday, Mar. 7th.—5.15 p.m.: Prof. Otto Meyerhof: Chemistry of Muscle in Relation to Problems of Cellular Physiology. (First two of four public lectures.)

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James Hospital, Ouseley-road, Balham, S.W.

Wednesday, Mar. 5th.—4 p.m., Dr. Charles E Larkin: Demonstration of Medical Cases.

NATIONAL HOSPITAL POST-GRADUATE COURSE, Queen-square, W.C.

Monday, Mar. 3rd.—12 noon, Dr. Greenfield: Pathology of Nervous System. 2 p.m., Dr. Riddoch: Out-patient Clinic. 3.30 p.m., Dr. Kinnier Wilson: Neurotubercle.

Tuesday.—2 p.m., Dr. Walshe: Out-patient Clinic. 3.30 p.m., Dr. Bernard Hart: Disorders of Personality.

Thursday.—2 p.m., Dr. Kinnier Wilson: Out-Patent Clinic. 3.30 p.m., Dr. Purdon Martin: Localising Signs of Tumours in the Cerebral Hemispheres.

Friday.—12 noon, Dr Purdon Martin: Anatomy and Physiology of Nervous System. 2 p.m., Dr. Adie: Out-patient Clinic. 3.30 p.m., Dr. Greenfield: Cerebro-spinal Fluid in Diseases and Injuries of the Skull.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

Tuesday, Mar. 4th.—5 p.m., Dr. W. Griffith: Eczema (1).

Thursday.—5 p.m., Dr. W. Griffith: Eczema (2).

ROYAL DENTAL HOSPITAL OF LONDON, Leicester-square, W.C.

WEDNESDAY, Mar. 5th.—6 P.M., Mr. Bowdler Henry: The Inter-relationship of the Mouth and the Bowel.

ANCOATS HOSPITAL POST-GRADUATE COURSE, Mill-street, Manchester.

THURSDAY, Mar. 6th.—4.15 P.M., Mr. E. E. Hughes: Vesical Calculus.

ST. MARY'S HOSPITALS, Manchester.

FRIDAY, Mar. 7th.—4.15 P.M. (at the Whitworth Street West Branch), Post-graduate Lecture, Dr. W. R. Addis: Breech Presentations.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, Mar. 4th.—4.15 P.M., Dr. F. E. Tylecote: Treatment of the Cirrhosis of the Liver.

FRIDAY.—4.15 P.M., Dr. Crighton Bramwell: Demonstration of Medical Cases.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

FRIDAY, Mar. 7th.—3.30 P.M. (at the Royal Infirmary), Mr. T. B. Mouat: Surgical Infection of the Urinary Tract.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

WEDNESDAY, Mar. 5th.—4.15 P.M. (at The Lock Hospital, 41, Rotten Row), Dr David Watson: Female Venereal Diseases.

Appointments.

ADAMSON, OSWALD J. W., M.R.C.S., L.R.C.P., has been appointed Honorary Clinical Assistant to the Sussex Eye Hospital.

Vacancies.

For further information refer to the advertisement columns.

All Saints' Hospital for Genito-Urinary Diseases, 91, Finchley road, N.W.—H.S. At rate of £150.

Ashton-under-Lyne District Infirmary.—H.S. At rate of £150.

Bedford County Hospital.—Asst. H.S. £130.

Birkenhead General Hospital.—Sen. H.S. and H.P. At rate of £150 and £100 respectively. Also Cas. O. £100.

Birkenhead Union Infirmary.—Res. Asst. M.O. £200.

Birmingham and Midland Eye Hospital.—Res. Surg. O. £150.

Birmingham Ear and Throat Hospital.—H.S. At rate of £150.

Birmingham, Erdington House.—Res. Asst. M.O. £250–£350.

Birmingham, Queen's Hospital Medical Schools.—Three H.P.'s. H.S. Anæsthetist. Also Dental H.S. Each £70.

Birmingham, Queen's Hospital.—Pathologist and Two Cas. Surgs. Each £100.

Blackburn and East Lancashire Royal Infirmary.—Fourth H.S. £130.

Bootle Borough Hospital.—Two Jun. H.S.'s. Each at rate of £150.

Bristol Eye Hospital.—H.S.

Burnley, Victoria Hospital.—H.P. At rate of £125.

Cardiff Royal Infirmary.—H.S. At rate of £50.

Carlisle City.—Asst. M.O.H. £750.

Carlisle, Cumberland Infirmary.—H.P. At rate of £155.

Central London Ophthalmic Hospital, Judd-street, W.C.—Hon. Dental Surgeon.

Charing Cross Hospital, W.C.—Med. Reg. £150. Asst. Reg. £100. Also Registrar to Ear, Nose, and Throat Dept. £100.

Connaught Hospital, Orford-road, E.—Sen. Res. M.O. At rate of £150. Also Res. H.S. and H.P. Each at rate of £100.

Derby, Derbyshire Royal Infirmary.—Ophth. H.S. £150.

Dreadnought Hospital, Greenwich.—Phys. in charge of Out-Patients.

Edinburgh Hospital for Crippled Children.—Surgeon. £1000.

Edinburgh Royal Infirmary.—Tutor and Sen. Clin. Asst. for Ophth. Dept. £145.

Evelina Hospital for Children, Southwark, S.E.—H.S. At rate of £120.

Exeter City.—Asst. Tuber. O. and Asst. M.O.H. £600.

Great Yarmouth General Hospital.—Sen. H.S. £150.

Hastings County Borough.—Deputy M.O.H. and Deputy School M.O. £600.

Hereford, Herefordshire C.C., Ross Urban and Ledbury and Ross Rural District Councils.—Asst. County M.O. and M.O.H. £685.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each at rate of £100.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W. Asst. Phys.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Ipswich, East Suffolk and Ipswich Hospital.—Two H.S.'s. Each £120.

King's College Hospital, Denmark Hill, London, S.E.—M.O. for Gonorrhœa Dept.

Kingston-upon-Hull, City Fever Hospital and Sanatorium.—Med. Supt. £800.

Kingston-upon-Hull, City and County of.—Tuberculosis Officer. £800.

L.C.C. Mental Hospitals Service.—8th Asst. M.O. £445.

Leicestershire and Rutland Mental Hospital, Narborough.—Med. Supt. £800.

Leicester Royal Infirmary.—Two H.P.'s, also H.S.'s. Each £125

Liverpool, St. Paul's Eye Hospital.—H.S. At rate of £120.

London Hospital.—Director of Dept. for Venereal Diseases. £800.

Macclesfield General Infirmary.—2nd H.S. At rate of £150.

Maidstone, Kent County Ophthalmic and Aural Hospital.—Ophth. H.S. At rate of £200.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

Manchester Royal Children's Hospital.—Two Asst. M.O.'s for. Out-Patients' Dept. Each at rate of £150. Also Res. Surg. O. At rate of £125.

Manchester Royal Eye Hospital.—Jun. H.S. £120.

Manchester, St. Mary's Hospitals.—Four H.S.'s to Special Depts. Each at rate of £50.

Middlesex Hospital, London, W.—Surg. Also Asst. Surg.

Miller General Hospital, Greenwich, S.E.—Res. M.O., Cas. O., and H.P. At rate of £250, £150, and £125 respectively.

Northampton General Hospital.—Two H.S.'s, also Two Asst. H.S.'s. Each at rate of £150.

Poplar, Metropolitan Borough of.—Temp. Asst. to M.O.H. £600.

Putney Hospital.—Res. M.O. £150.

Queen Mary's Hospital for the East End, E.—House Anæsthetist and H.P. At rate of £120.

Rochester, St. Bartholomew's Hospital.—H.P. At rate of £175.

Royal National Orthopædic Hospital, Great Portland-street, W.—H.S. At rate of £150.

Royal Northern Hospital, Holloway, N.—H.P. Also Obstet. H.S. Each at rate of £70.

Royal Society, Burlington House, W.—Smithson Research Fellowship. £800.

St. John's Hospital, Lewisham, S.E.—Res. H.S. £100.

Salford Royal Hospital.—H.P. Two H.S.'s. and Cas. H.S. All at rate of £125.

Scarborough Hospital and Dispensary.—Two H.S.'s. At rate of £126.

Sheffield University, Dept. of Pathology and Bacteriology.—Asst. Bacteriologist. £300.

Southampton Children's Hospital and Dispensary for Women.—Res. M.O. At rate of £100.

Southampton County Borough.—Asst. M.O.H. £600.

Southampton, Royal South Hants and Southampton Hospital.—Jun. H.S. Also Cas. O. At rate of £130 and £120 respectively.

Truro, Royal Cornwall Infirmary.—H.S. £170.

West London Hospital, Hammersmith-road, W.—H.P., Two H.S.'s and Res. Anæsthetist. Each at rate of £100. Hon. Asst. Surg., Hon. Med. Reg., and Hon. Obstet. Reg.

Westminster Hospital, Broad Sanctuary, S.W.—Clin. Asst. to Dental Dept. Also Sen. Res. and Cas. O., H.S. to Eye, Ear, Nose, and Throat Dept. Also Asst. Med. Reg. At rate of £104, £102, and £100 respectively.

Willesden General Hospital, N.W.—Clin. Assts.

Willesden U.D.C.—Two Dentists. £572 6s. 4*d*. Also Part-time Anæsthetist and Part-time Oculist. At rate of £300 and £225 respectively.

Windsor, King Edward VII. Hospital.—Res. M.O. £200. Also Sen. H.S. £140.

York County Hospital.—H.S. £150.

The Chief Inspector of Factories announces the following vacant appointments for certifying Factory Surgeons: Denny (Stirling), Eckington (Derby), Halifax (Yorks), Halstead (Essex), and Haverfordwest (Pembroke).

Births, Marriages, and Deaths.

BIRTHS.

BATTERHAM.—On Feb. 21st, at Keyberry House, Newton Abbot, Devon, the wife of Dr. Douglas Batterham, of a son.

ROWLEY.—On Feb. 18th, at St. Brenda's, Clifton, Bristol, the wife of Dr. Rowley, of Wrington, Somerset, of a daughter.

MARRIAGES.

BUMSTED—ROBERTSON.—On Feb. 22nd, at Trinity (Presbyterian) Church, Streatham, Henry James Bumsted, M.A., M.B., B.C., to Margaret Helen, daughter of the late Sutherland Robertson and Mrs. Robertson, of Norbury-crescent, Norbury, S.W.

ROCHE—HUGHES.—On Feb. 18th, in London, Hilary Roche, M.D., M.R.C.P., to Janet Hughes, daughter of Mr. and Mrs. G. Reeves-Smith, Berkeley-street, London, W.

DEATHS.

BASHALL.—On Feb. 19th, at Claremont-road, Surbiton, Charles Edward Bashall, M.R.C.S., L.R.C.P., aged 64.

BILL.—On Feb. 21st, at Davos, Switzerland, Arnold Francis Bill, M.D., aged 64.

CARTER.—On Feb. 21st, suddenly, at Westfield Park, Redland, Bristol, Thomas Moravian Carter, O.B.E., T.D., M.D., aged 61.

FOLEY.—On Feb. 18th, at Worthing, after more than two years illness, Mabel Foley, L.M.S.S.A., aged 63.

LUCAS.—It is with deep regret we have to announce the sudden death of Dr. Gordon Lucas, of Dartford, who passed away at the early age of 27, on Monday morning, 24th inst., after a very short illness, in Westminster Hospital.

TUBBY.—On Feb. 23rd, Colonel Alfred Herbert Tubby, C.B., C.M.G., M.S., F.R.C.S., of The Albany, Hastings, Consulting Surgeon to Westminster and the Royal National Orthopædic Hospitals, aged 67.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

LAVERAN JUBILEE CELEBRATION IN NAIROBI.

THE annual meeting of the Kenya Branch of the British Medical Association this year took the form of a jubilee to celebrate the discovery of the malaria parasite by Alphonse Laveran 50 years ago. Members attended from all parts of the Colony at sessions on three afternoons (Jan. 15th–17th, 1930) devoted to the consideration of various aspects of malaria. The President, Dr. J. H. Sequeira, opened the conference with a historical sketch of Laveran and his place in scientific medicine, and gave a brief account of the developments which followed his discovery. Dr. Kauntze gave a lantern demonstration of the blood changes in the several types of the disease, and Mr. Symes described the incidence of the types of anopheles found in Kenya Colony. The second day was devoted to the clinical aspects of malaria, Dr. G. V. Anderson describing the protean forms under which the disease occurs in Europeans, while Dr. Procter gave a résumé of observations made in the Africans in the native reserves. The major portion of this session was taken up by a debate on the treatment of malaria and blackwater, opened by the Hon. Dr. J. L. Gilks, the Director of the Medical and Sanitary Services in the Colony. Many members participated in a useful and profitable discussion.

The third day was dedicated to preventive measures, and was opened by Dr. Paterson with a historical account of the conditions which led to the disappearance of malaria in those parts of the United States in which pioneer conditions obtained essentially similar to those met with in some parts of the colony. Mr. Leigh-Bennett, the Antimalaria Engineer, read an instructive paper on soils and drainage. Dr. Steel, of the Tanganyika Medical Service, and Dr. de Buer, who has done much good work at Mombasa, discussed the measures suitable for towns, and Dr. Philip gave an account of the measures required in certain native reserves to render the population, debilitated by worm-infection, especially ankylostomiasis, fit to undertake the housing and other improvements required to combat the malarial infection.

The annual dinner, at which 80 members and guests attended, was held at the New Stanley Hotel. H.E. the Governor was represented by the Colonial Secretary, Mr. Monck-Mason Moore.

The Medical Department of the Colony during the week held a Health Exhibition at the Memorial Hall, showing graphically by specimens, models, pictures, &c., how to make Africa healthy. The Governor opened the Exhibition, and he was accompanied by Mr. Neville Chamberlain, who gave an address. No fewer than 15,000 persons, European, Asiatic, and African, attended this educational demonstration of practical hygiene.

NEW PREPARATIONS.

DIGITALIS LEAF TABLETS (Allen and Hanburys, Ltd. Bethnal Green, London E.2).—This is a preparation of digitalis leaves whose physiological standardisation is valuable because it is recognised that digitalis leaves of different batches do not contain necessarily the same proportion of active principles. At the Geneva Conference of 1925 it was decided to adopt as an international standard a mixture of ten different specimens of digitalis leaf, the final mixture being carefully assayed. Preparations, like this, adjusted to the international standard can be relied on to have an unvarying therapeutic activity, and the new drug is presented in a convenient form for prescribing. Tablets Digitalis (A. and H.) each contain 0·033 gramme ($\frac{1}{2}$ grain) International Standard digitalis leaf equivalent to $\frac{1}{3}$ of an International Unit. The recognised daily dose is $\frac{1}{3}$ to 1 International Unit—i.e., one to three tablets. They are supplied in bottles of 100.

SUNNYCOMB (Macfie and Sons, Ltd., 34, Moorfields, Liverpool).—This is a pure invert sugar, a palatable mixture of dextrose and lævulose, suitable for infant food and prepared from sugar cane under close supervision. Its composition is as follows: dextrose 37·5 to 38·5 per cent.; lævulose, 35 to 36 per cent.; sucrose 1 to 3 per cent.; iron, 0·01 to 0·03 per cent.; lime, 0·01 to 0·03 per cent. We have received satisfactory reports on its use, and it can replace sugar for most purposes—e.g., in coffee or with stewed fruit or, as a change from jam, on bread.

ERBOLIN CAPSULES (Stafford Allen and Sons, Ltd., Cowper-street, Finsbury, London, E.C.).—Erbolin is a physiologically standardised and stable ergot, and the preparation should be valuable in view of practical experience with the extract Ergotæ Liq. B.P. Erbolin is powdered ergot in capsule form, and each capsule contains the equivalent of 0·5 mg. (1/200 grain) ergotoxine phosphate. This composition has been determined by a biological test carried out through the Pharmaceutical Society of Great Britain. The capsules are issued in packages of 100, 500, and 1000, duly labelled poison.

"GOSSAMATEX."

THIS is a fabric which has been brought to our attention by the firm of T. M. Lewin, 39, Panton-street, Haymarket. It washes well and does not shrink. It can be supplied in all kinds of materials and garments, in plain or coloured fabrics, and can be made to order. Considerable hygienic claims are made for this substance, and its protective value is certainly aided by its porosity. It is very light and pleasantly soft to wear.

THE CHILD'S DEVELOPMENT.

WE have received a copy of a revised and enlarged edition of "The Progress Book," being an illustrated register of the child's development from birth till coming of age and after by Mr. W. M. Pilley, M.A., printed for Mellins Food Ltd. and published by Mears and Caldwell (Cranmer-road, London, S.W. 9). It is a squarish book of 144 pages containing space to record details of the child's birth, family history, growth in weight and height, important happenings in early life such as his funny sayings and the first attendance at Sunday School, his educational record, leading on to recreations and amusements, clubs and associations joined, with sections for a running account of health and character, and for the insertion of photographs at every year of life, We miss, however, any place of entry for the first and last caning which, as recent correspondence has shown us, plays still such a large part in the upbringing of adolescent boys and even girls. Apart from blank spaces to fill in, there are suggestions of suitable names for boys and girls, what books to read at various ages, and the appropriate speed to gain weight and height. Such intimate details will afford parents pleasure both in recording and recalling, and, should little Willie become a Shakespeare or baby Florence a Nightingale, the record will have retrospective value for the world at large.

"FISGARD."

To the Editor of THE LANCET.

SIR,—The letter of "Etymologist" in THE LANCET of Dec. 14th, 1929, p. 1292, asking for the origin of the word "Fisgard" as the name of a ship, has probably been answered before now. If, however, it has been overlooked, the following quotation from Wheeler and Broadley's "Napoleon and the Invasion of England," Vol. I., p. 52, may suffice: "The *St. Fiorenzo* was appropriately rechristened the *Fisgard* (Fishguard), and in the latter part of the last century was still the receiving ship at Sheerness." The change of name was, of course, in commemoration of, or rather in jubilation over, the easy victory over the French force of about 1200 men under the American Colonel Tate, who landed at Fishguard on Feb. 22nd, 1797, and surrendered ignominiously two days later. Colonel Tate received his orders from Admiral Hoche after the failure of the latter to land and carry on war in Ireland. Details may be found in the book above mentioned, and in many others.

I am, Sir, yours faithfully,
F. LUCAS BENHAM, M.D.

Semaphore, South Australia, Jan. 21st, 1930.

⁂ A letter from "Sea Captain" on this subject appeared in THE LANCET of Dec. 21st, 1929.—ED. L.

ALEXANDRA DAY.

WE are informed by Miss C. May Beaman, C.B.E., the organiser of Alexandra Rose Day, that her address is 33, The Grove, The Boltons, London, S.W.10, and not as previously announced.

THE LITESOME BODY-BELT.

THE Litesome is a body-belt with a scrotal pouch attached made of a washable and unshrinkable woollen material. The suspender is an appliance which not only the subjects of varicocele but the pursuers of many field sports find serviceable, and this belt is well made and should prove comfortable, if a little hot for wear in warm weather.

WE regret that in a report of a discussion on Intrathoracic Tumours, at the Section of Surgery of the Royal Society of Medicine (THE LANCET, Feb. 15th, p. 350), the statements made by Mr. A. Dickson Wright were wrongly attributed to Mr. W. A. White, whose name does not appear on the Medical Register.

Milroy Lectures
ON THE
INCIDENCE OF RHEUMATIC DISEASES.

Delivered before the Royal College of Physicians of London

BY J. ALISON GLOVER, O.B.E., M.D. CAMB.,
M.R.C.P. LOND., D.P.H.,
A MEDICAL OFFICER OF THE MINISTRY OF HEALTH.

LECTURE I.—THE INCIDENCE OF ACUTE RHEUMATISM.

Delivered on Feb. 27th, 1930.

MR. PRESIDENT AND GENTLEMEN,—The founder of these lectures, Dr. Gavin Milroy, in his suggestions for their purpose, desired that they might deal "with chronic constitutional diseases, and with the vast amount of protracted malaise and suffering, disablement or lessened capacity for industrial work, and often, too, of slow but eventually fatal disease." These words aptly apply to the chronic rheumatic diseases, whilst acute rheumatism is now regarded as a specific infectious disease, of great importance in State medicine.

In my first lecture I propose to deal with the incidence of acute rheumatism; in my second to try to resolve "industrial rheumatism" into its constituent parts—a problem which may involve a brief discussion on classification—and to estimate the incidence of non-articular fibrositis; in my third I shall discuss the incidence of various forms of chronic arthritis.

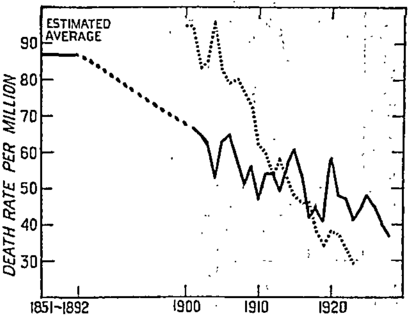
The observation of Sir William Church concerning acute rheumatism, that "it is almost impossible to form any opinion as to the frequency of its occurrence in the United Kingdom," remains only too true, even though we now have new sources of information in national insurance and the school medical service, sources not available to Church, Longstaff, or Newsholme.[1] These advantages, however, do not outweigh the difficulties added in recent years by the enlargement of the diagnosis to include many conditions not previously regarded as rheumatic fever.

MORTALITY STATISTICS.

The immediate mortality of acute rheumatism is very low, generally under 1 per cent. Even in hospitals where the worst cases are admitted, the case-mortality seldom exceeds 2 per cent., save in children's hospitals, where the case-mortality has reached 13 per cent.[2] in certain outbreaks. In England and Wales the deaths at all ages from rheumatic fever and chorea together formed only 0·34 per cent. of the total deaths alike in 1927 and in 1928, whilst for ages under 15 they account for 0·8 per cent. of all deaths (or 0·7 rheumatic fever alone). If, however, we look only at that interesting period of life between 10 and 15 years, the age of adolescence, and the age at which the acute rheumatic infection is most fatal, we see a different picture. In this age-group acute rheumatism causes 5·4 per cent. of all deaths, and heart disease (80 per cent. of which at this period is due to rheumatic carditis) 10·8 per cent., or together 16·2 per cent., four-fifths as much as all forms of tuberculosis (20·7 per cent.) and more than twice as many as measles, scarlet fever, and diphtheria together (7·1 per cent.).

Fig. 1 shows the cheering fact, well known but somewhat unappreciated, that the mortality figures for rheumatic fever for England and Wales have shown a steady fall in the crude death-rate (persons) per million living from 67 in 1901 to 38 in 1928, which is the lowest on record. Allowing for the change of classification in the Registrar-General's returns in 1881 when acute rheumatism was first separately returned, the mean death-rate for the period 1851 to 1892 may be taken as somewhere in the neighbourhood of 87. Sir Arthur Newsholme[1] in his Milroy Lectures of 1895 noted that the curve of its prevalence as judged by hospital admissions formed "an elevated plateau with undulations from 1868 to 1874 then a sloping declivity, also with minor undulations, from 1874 to 1889." But from 1889 to 1895 there was a somewhat steady rise and from it Sir Arthur surmised that since 1889 "the upward gradient of a second similar wave" of prevalence had commenced. We are now able to see, however, from mortality, hospital, and morbidity statistics alike that, although minor undulations have continued, both incidence and virulence have continued steadily to decline. Moreover, the mortality from heart disease in every age-group in which rheumatic heart disease is the main factor shows considerable reduction, thus supporting the other evidence that acute rheumatism is declining in frequency and virulence. For all ages under 65 the rates for each sex in 1927 are less than those in the decade 1911-20, and in the younger ages under 35 as much as one-third less. It is only in the rates for ages over 65 that the increase in heart disease mortality is seen, but so large is this increase (mainly due to an increased specification of myocardial degeneration[3] (over 75) in death certificates) that it causes the heart mortality-rate for all ages to show increase, in spite of the decrease in the younger ages.

FIG. 1.

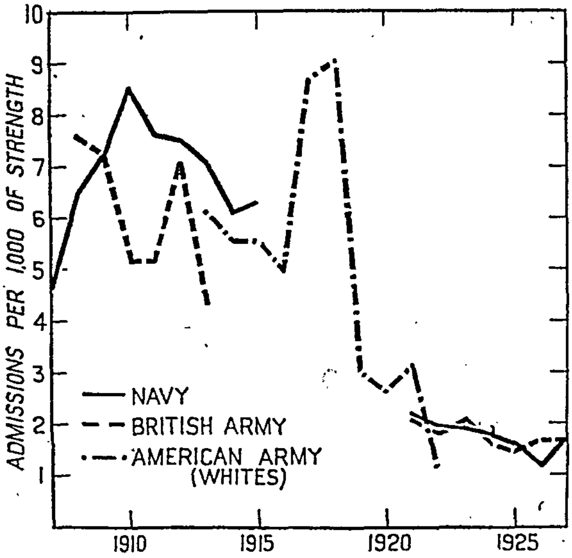


Rheumatic fever crude death-rates, per million living persons, in England and Wales (continuous and interrupted lines), and in the United States registration area (dotted line). The English figure for 1851 to 1892 is an estimated average. The American figures are those given by R. M. Atwater.

In Fig. 1, as I have said, the descent from 67 per million in 1901 to 38 in 1928 (43 per cent. in 27 years) will be seen, and, although epidemic peaks occur in 1901, 1906, 1914, and a sharp one (that described by Dr. Poynton[2]) in 1920, it will be noted that each epidemic peak is lower than the preceding peak. The dotted line shows a similar decline in the *rheumatic fever* death-rate[4] in the United States registration area—a decline at first sight even more striking, for it is from 95 per million in 1901 to 30 in 1923, but in which, although the decline is a real one, there are, as Atwater points out, some unreal factors not present in the English decline. These factors are due to two changes in classification and to the inclusion of certain Southern States with low rates, but even if they account at a liberal estimate for, say, one-third of the apparent fall, the real fall must be substantial.

Galabin[5] and Longstaff,[6] and more recently Atwater,[4] have shown that the trend and the oscillations of the mortality from rheumatic fever show striking statistical analogies with those of scarlet fever, erysipelas, septicæmia, and puerperal fever, resemblances in epidemic incidence extending over 75 years. "Certain years," says Atwater, "prove good years for all, as though the diseases were crops affected by the same influences, while other years prove poor years. Acute rheumatic fever appears to be related to the family of streptococcal infections, because of bacteriological indications, clinical resemblances, and epidemiological kinships."

FIG. 2.



Admission to hospital for rheumatic fever in the Regular Services. British figures are not available for the period of the late war.

NOTIFICATION.

Compulsory notification of cases is still almost confined to Norway (towns only with an aggregate population of about 800,000), Denmark, and Iceland.

The Norway returns show (*a*) a remarkably constant annual attack-rate of 1·5 per 1000; (*b*) a low case-mortality ratio of 0·87 per cent. seven years average, or 0·5 in 1927; (*c*) a characteristic seasonal incidence with a well-marked summer minimum usually in July, and a winter maximum; and (*d*) a striking correspondence with tonsillitis which is also notifiable. This correspondence between tonsillitis and acute rheumatism in seasonal incidence is also seen in English and American statistics.

The Denmark notification figures show a decline of more than 50 per cent. since the nineties, for, whereas the average for the 24 years 1870–93 was 2·18 (Newsholme[1]), during the last five years it has been just over 1 per 1000, and shows little variation. There is some correspondence with the tonsillitis curve as in Norway, but there is less rheumatic fever in proportion to the tonsillitis notified.

Rheumatic fever in Iceland is of a mild and unusual character, with an average attack-rate of 1·25 per 1000 per annum. The incidence seldom runs parallel with that of acute tonsillitis, and the disease is seldom followed by endocarditis. In 1926, for example, of 146 cases notified from a population of 100,117, not one was notified as having cardiac complications.[7] In Iceland, salicylates seem to have but a slight effect upon the disease, and it is suggested that some of the cases notified as rheumatic fever may really be of tuberculous origin (Poncet's form of rheumatoid arthritis). The incidence is three times as great on females as on males, a proportion which certainly suggests a good deal of rheumatoid arthritis, and contrasts strongly with Norwegian experience, where the notifications are equally divided between the sexes. Thus, in ten years (1913–22) in Oslo[8] there were 828 cases of rheumatic fever in males and 815 in females.

In England an experiment in compulsory notification of acute rheumatism in children is in progress in three metropolitan boroughs—Paddington, Kensington, and Holborn, but it is too soon to judge whether the success of these limited trials of compulsory notification will justify a more extended experiment.

EXPERIENCE IN THE SERVICES.

The *Health Reports of the Services* furnish some useful statistics.

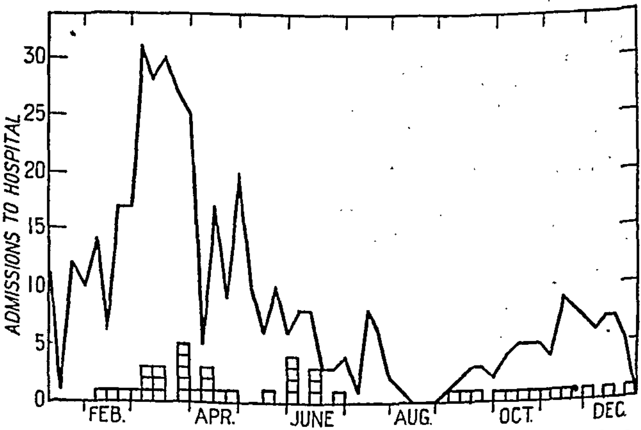
The Army admission-rate has dropped 60 per cent., from 4·3 per thousand in 1913 to 1·7 in 1927, whilst for the Home Army an attack-rate of 5 in 1913 has fallen to 1·9 in the same period. The attack-rate for young insured males (16–24) in the Ministry's inquiry was 1·5 per 1000, a very similar rate. The Royal Navy admission-rate has dropped 78 per cent., from 7 per thousand in 1913 (when "rheumatic fever" was first separately returned from "rheumatism") to 1·7 in 1927, whilst the Royal Air Force admission-rate in 1927 was 0·9. More exact diagnosis may have had some influence in these Service reductions.

The American Army[9] attack-rate shows a very similar reduction of 82 per cent., from 6·2 per thousand in 1913 to 1·1 in 1922, that is for white regular soldiers only, stationed in the Home Country. The admission-rate for negro regular soldiers in the Home Country has only fallen 29 per cent., from 4·1 in 1913 to 3·1 in 1922.

Fig. 2 shows the fall in the attack-rate for the British Army and Navy after the war, and upon it I have inserted a curve showing the incidence for white regular soldiers in the American Army at home. This American curve, although it applies only to regulars serving at home, shows the considerable increase during the two years (1917 and 1918) of intensive mobilisation in the United States, an increase no doubt due to the conditions of overcrowding and new entry consequent upon the sudden creation of a great army.

Surgeon-Captain T. B. Shaw[10] has shown that the reduction in the admission-rate for acute rheumatism in the Navy has not been accompanied by a corresponding decrease in the admission-rates for tonsillitis, which has only fallen from 46 per thousand in 1923 to 36 in 1927, whilst the rheumatic fever rate has fallen from 4·7 to 1·7. In the Army, the tonsillitis rate appears actually to have risen, so that, whereas in 1913 one case of acute rheumatism was admitted to hospital for about every five of tonsillitis, in

FIG. 3.



Epidemic of acute rheumatism at Halton, 1928, shown by admissions to hospital each week. The columns represent acute rheumatism cases, and the line represents cases of tonsillitis and nasopharyngitis. Note that the crest of the tonsillitis wave precedes the crest of the acute rheumatism wave by some three weeks. Total population 3530, of whom 2441 were boys 16–18 years; among these the acute rheumatism attack-rate was 14·3 per 1000.

1926 and 1927 20 cases of tonsillitis were admitted for every case of acute rheumatism. Here again fashion in diagnosis, such, for example, as a transference to tonsillitis of some conditions previously diagnosed P.U.O. may have had some effect.

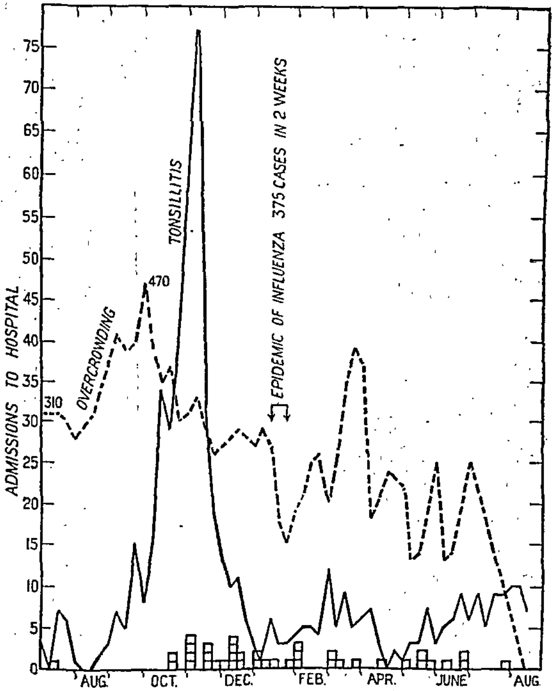
The improved conditions of hygiene in the Services is apparently bringing them into a condition similar to that of our great public schools, in which epidemics of tonsillitis still occur not infrequently but without acute rheumatism. Nevertheless, acute rheumatism still sometimes occurs in epidemic form in the Services. Grenet[11] in 1920 reported five distinct epidemics in the French Army and gave evidence of bed-to-bed infection. The annual report on the health of the Navy has shown high attack-rates at some of the Royal Naval Training Establishments, such as those at Shotley, 14·9 per 1000 in 1925, 13·6 in 1926, and 22·5 in 1927, and shows how closely the attack-rate is correlated with pressure on accommodation.

Dudley[12] has shown the similarity of the incidence of pneumonia and acute rheumatism at Shotley, and the fact that overcrowding and rapid rate of change of population are contributory causes. He considered, however, that damp and chill are a much more important factor than overcrowding in the incidence of rheumatic infections. Dudley[13] also describes the conditions at the training establishment *Impregnable* in 1912–13. He shows that the boys all entered at 15½ years for nine months' training, so that the population was entirely changed during that period. They were housed in three old wooden battleships, one reserved for new entrants. The sleeping accommodation was between decks, on which there was almost no break in the continuity of air space. The hammocks were 16 inches apart, many close to the deck above. All these conditions were peculiarly favourable for droplet infection, whilst the continual influx of new individuals prevented any lasting rise in herd immunity to a specific infection. The annual attack-rates per 1000 were 397 for tonsillitis and 43·7 for rheumatic fever, pneumonia being 35·3. Incidence was heaviest on newcomers.

Other factors are fully discussed by Dudley, and the whole story, now happily ended by the transference of the boys in 1923 to barracks ashore, supports the theory that acute rheumatism is a specific infectious disease of low-grade infectivity conveyed by droplet infection.

An interesting epidemic of acute rheumatism is referred to in the Report on the Health of the Royal Air Force for 1928. At the training establishment at Halton, out of a total strength of 3530, 2441 were aircraft apprentices, who train there for two years all picked boys of a superior class, between the ages of 16 and 18, housed in dormitories, each of which contained 21 beds, in modern buildings. Beginning in February, 1928, there was a sharp epidemic of tonsillitis, 427 cases (175 per 1000) being admitted to hospital. Forty-one cases of acute rheumatism occurred, in 17 (41 per cent.) of which carditis was observed; all but 6 of the 41 patients being aircraft apprentices. By the kind permission of the Director of Medical Services, R.A.F., I have been able to chart the weekly admissions for acute rheumatism and for tonsillitis. Fig. 3 shows that the peak of the tonsillitis epidemic precedes by some two to three weeks the crest of the acute rheumatism epidemic.

FIG. 4.



Epidemic of acute rheumatism, 1926–27. The columns represent admissions to hospital for acute rheumatism (1 square = 1 case). The continuous line shows the admissions for tonsillitis. The interrupted line shows the curve of overcrowding. (Base line = authorised complement. Scale = ten times that for admissions to hospital.) Population about 2000 boys, all 16 years of age. Note that the overcrowding crest precedes the tonsillitis crest, which in turn precedes the crest of the acute rheumatism curve.

AN INSTRUCTIVE OUTBREAK.

Leaving now the Royal Air Force, Fig. 4 illustrates an epidemic in the winter of 1926–27 which occurred in a community consisting of some 2000 boys, all entering at 16 years of age, after a strict medical examination, to undergo a nine months' course of strenuous training. There was a rapid and continuous flow of new entrants. The boys slept in long dormitories, mostly designed to accommodate 42 boys. At the period shown there was definite overcrowding, and there had previously been a good deal of acute rheumatism in the establishment. There were thus present all the factors for a droplet infection, when the season of epidemic prevalence should come round, a community of susceptible age, rendered the more susceptible by sudden transference from home conditions to a strenuous régime, a rapid continuous influx of new entrants, sleeping quarters each containing many boys, and somewhat overcrowded, thus facilitating that massive dosage and rapid transference of infection from person to person which seem to exalt the virulence of droplet infections, and lastly some convalescents or carriers remaining to carry over the infection from the last epidemic season. The epidemic season of late autumn being come, some three weeks after the most severe overcrowding, the epidemic potential, which had gradually developed, reached a critical value, and there was a sharp epidemic of tonsillitis, followed by an outbreak of acute rheumatism. Again we see the peak of the tonsillitis epidemic precedes the crest of the rheumatism wave by some two or three weeks. But it will be noted particularly that the crest of the overcrowding precedes the peak of the tonsillitis also by some two or three weeks. Cases continued for some time, dying down in July, and breaking out again in the next epidemic season.

PARALLELISM WITH CEREBRO-SPINAL FEVER.

These two diagrams (Figs. 3 and 4) strongly suggest that acute rheumatism is a specific infectious disease conveyed by droplet infection, and that it resembles cerebro-spinal fever in its epidemic incidence on a largely *immune population*. We may compare with them Fig. 5, a diagram of a cerebro-spinal meningitis epidemic[14] which occurred in a slightly older community of young recruits undergoing three months intensive training at the Guards' Depôt, Caterham, during the war. It will be seen how like to the tonsillitis curve is the "warning rise" in the carrier rate of the meningococcus which follows overcrowding, and how when the "carrier rate" passes the "danger line" of somewhere about 20 per cent.—in other words, when the "carrier epidemic" reaches a certain intensity—the "case epidemic" begins, and cases of cerebro-spinal meningitis occur. The meningococcus when "carried" does not usually produce either catarrh or tonsillitis, and the "warning rise" can only be demonstrated by regular bacteriological sampling on a large scale.

In the case of the two acute rheumatism epidemics, the "unseen" healthy carrier wave is probably present too, but in addition there are two "visible" waves, the larger the tonsillitis wave, and the smaller the acute rheumatism wave. But if this analogy be true, why did not outbreaks of rheumatic fever occur at Caterham Depôt alongside those of cerebro-spinal fever in January, 1917, and again in May, 1918, when overcrowding was so severe, new entrants so numerous, and conditions so surely favourable? This question came to me with such force that I obtained the kind permission of the War Office and the Ministry of Pensions to examine the records of Caterham Military Hospital, now in the custody of the latter. The cases of rheumatic fever did occur, at the same time, and in almost the same numbers as the cases of cerebro-spinal fever, as Fig. 5 shows. In the winter epidemic of 1917 there were 20 cases of cerebro-spinal fever and 21 cases of rheumatic fever,* but the latter attracted no such attention as was accorded to the cases of the dreaded and fatal "spotted fever," and though admirably treated clinically, were lost sight of epidemiologically.

The chart is especially valuable in that it shows that the occurrence of the cases of rheumatic fever was not due to seasonal prevalence, for during the next winter season, when the depôt had been rigorously "spaced out" as regards its beds, when there was no overcrowding, and ventilation had been improved in accordance with a scheme of prophylaxis against cerebro-spinal fever, not only did the meningococcus carrier rate fall almost to nil, not only were there no cases of cerebro-spinal fever, but also, with the exception of one case in November, there were no cases of acute rheumatism.

In April, 1918, however, came the German Advance, followed by the great "call up," and in May the depôt was more severely overcrowded than ever before. The meningococcus carrier rate shot up, five cases of cerebro-spinal fever occurred, followed by three cases of rheumatic fever. Fortunately, prompt action was taken as a result of the warning rise of the carrier rate, and the overcrowding was abated by the use of tents, and no doubt owing to this action, fine weather, and the fact that the epidemic season for both diseases was now past, no further cases occurred. The correlation between the overcrowding and the incidence of both diseases is very close. I do not suggest, of course, that there was any other connexion between the two diseases than that both as droplet infections reacted similarly to the same causes. The strain of new conditions seems to have been a highly important factor in producing susceptibility, for in all these epidemics the patients were not debilitated or "pre-rheumatic" children, but boys and men selected by recent medical examination as especially robust. No doubt these epidemics might be interpreted in different ways—as Prof. Major Greenwood has said of other epidemics: "They return to our serene questionings a great variety of answers, and we generally catch the answer that we wish to hear"—but to my mind the answer in these cases is clear, that acute rheumatism has been spread by droplet infection, and that its incidence was directly correlated with overcrowding.

The recent work of Cecil, Nichols and Stainby,[15] Carey Coombs,[16] and others seems to prove that acute rheumatism, like cerebro-spinal fever, is a bacteræmia at least in its early stages. Each disease thus seems to have a nasopharyngeal stage, a bacteræmial stage, and a stage where the organism reaches its characteristic locus, in the case of the meningococcus the cerebro-spinal fluid, in rheumatism the joints and heart.

DIRECT DROPLET INFECTION.

The theory that acute rheumatism is conveyed by droplet infection is further supported by its intimate association with tonsillitis and by its strong epidemiological likeness to scarlet fever, as has been seen in mortality statistics. Newsholme[1] gives an interesting summary of observations suggesting the infectivity of rheumatic fever, but concludes that direct infection *if it occurs is exceptional.*

Even in our great public schools, where acute rheumatism is now almost unknown, there is sometimes evidence to be obtained of direct droplet infection. Thus, a large boarding school for girls of the well-to-do class had been free from the disease for many years, when three cases occurred in the same term, and the same house. A boys' public school had three cases in one term, two in the same dormitory; there was a precedent epidemic of tonsillitis, and a too great proximity of beds. My impression is that such small outbreaks sometimes occur in institutions without investigation, and I should be very glad to hear of any instances.

The infectivity of acute rheumatism resembles that of pneumonia or cerebro-spinal fever, and just as the latter in non-epidemic times only occurs in sporadic cases in the most susceptible individuals, so acute rheumatism usually occurs sporadically in susceptible individuals. Thus the possibility of the transmission of acute rheumatism by droplet infection has been lost sight of, even after St. Lawrence showed in his study of the "Family Association of Rheumatism," that in families having one member the subject of the disease, rheumatic infection exceeds tuberculosis alike in family incidence and in frequency among exposed persons. St. Lawrence[17] found that in his 100 rheumatic families the percentage of cases among exposed persons who might have been infected from the patient was 14·8 per cent. in rheumatic infection, whilst the corresponding figure with 100 families in the case of tuberculosis was 14·6 per cent. The corresponding percentage in the Medical Research Council Committee's Report for rheumatic infection was 15. The Committee[18] express the guarded view that, on the whole, while it cannot be said that there is, in the facts collected, any conclusive evidence of contagion, many of them are consistent with this view.

---

* Three cases of recurrence of previous acute rheumatism in old N.C.O.'s (each of whom had two recurrences) are omitted.

The theory of droplet infection in rheumatism does not in fact seem to have received much favour from English physicians. Dr. Reginald Miller,[19] who has done a great work for the rheumatic child in this country, for example, says that "there is no such tradition on the side of clinical medicine" as the theory of possible contagion in acute rheumatism, and again, "rheumatism is not a contagious disease." In their admirable recent work M. Campbell and E. C. Warner[20] show that 58 per cent. of rheumatic children have immediate relatives suffering from acute rheumatism, compared with 24 per cent. of non-rheumatic children of the same poor hospital out-patient type, and that while it is rare for a non-rheumatic child to give a history of more than one relative with rheumatism, it is extremely common for rheumatic children to do so. They quote families where all four children are rheumatic and where three out of four children are rheumatic. And yet all this is ascribed to heredity; familial infection is not discussed or even mentioned. So that while other views, heredity, damp housing, deficiency in diet, all no doubt important causal factors, have received great attention in this country, the teaching of St. Lawrence has been somewhat discounted.

> "Thus," says Dudley, "acute rheumatism, and to a less extent pneumonia are interesting examples of how the infective nature of a clinical syndrome may be masked, if a definite environmental complex is essential before a parasite can call forth that special set of reactions of the host which has been dignified with a special name."

In the hope that the importance of droplet infection in acute rheumatism will receive greater attention, I have therefore emphasised these epidemics at the cost of omitting many better-known aspects of the incidence. The theory of droplet infection, far from denying the influence of heredity, defective diet, damp housing, or poverty upon the incidence of acute rheumatism, helps us to understand the nature of their influence. The incidence is determined by two sets of factors. The first cause massive dosage and include overcrowding, close contact, as by sleeping in the same bed, defective ventilation and catarrhal diseases increasing the infectors spraying capacity. The second set of factors are those which lower the immunity of the individual and of the herd, those affecting the individual including rheumatic heredity, new entry to the infected community, defective diet, especially the lack of vitamin A, dampness† of house or site, chill, fatigue and antecedent diseases, that affecting the community a rapid influx of new entrants. Poverty, especially in urban conditions, is the parent of nearly all these factors, and so acute rheumatism is a disease of poverty and of towns.

THE SOCIAL INCIDENCE.

No disease has a clearer cut "social incidence" than acute rheumatism, which falls perhaps thirty times as frequently upon the poorer children of the industrial town, as upon the children of the well-to-do. This subject has been fully discussed in the recent report[18] of the Child Life Committee of the Medical Research Council. I agree, however, with those who hold that the incidence of acute rheumatism increases directly with poverty, malnutrition, overcrowding, and bad housing. I do not agree with those who hold that the incidence is greater in the artisan class or in those just above the poverty line than in the classes below that line. The high incidence of acute rheumatism shown in Fig. 6 (adapted from G. Danieschewski[22]) in the city of Moscow may be in part due to poverty, deficient diet, and overcrowding. Danieschewski finds a still higher incidence in the agricultural districts around Moscow.

Heredity is an important factor but familial infection is at least as important; examination and supervision of familial contacts appears desirable.

> "A review," says Atwater,[4] "of the epidemiology of acute rheumatic fever indicates from many angles that this disease is one of the communicable infections caused by a living parasite which gains access to the body from without, and which produces a disease picture in which the age, sex, seasonal, racial, and other characteristics are fixed, and being close in their resemblance to the well-known epidemic diseases. Taken with the recently confirmed evidence of multiple cases in rheumatic families, we may well agree with Hirsch that rheumatic fever deserves an assured place among the active infective diseases."

In a large proportion, perhaps 70 per cent., of cases,

FIG. 5.

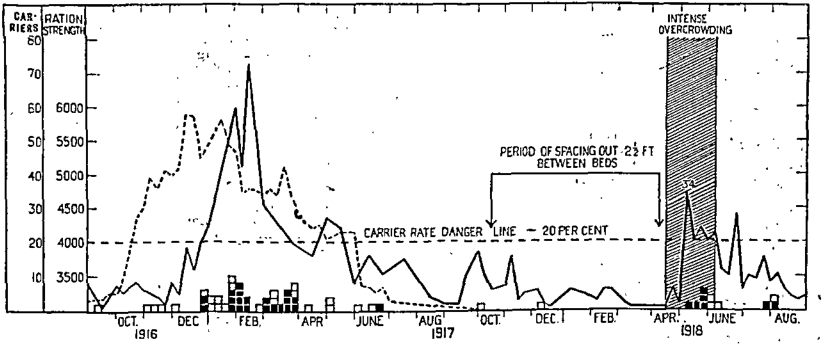


Diagram showing the effect of overcrowding in producing (1) cerebro-spinal fever (each case = 1 black square), and (2) rheumatic fever (each case = 1 white square). The continuous line represents the percentage carrier-rate of the meningococcus (each line = 2 per cent.). The dotted curve represents the ration strength. When this passes 4600 the overcrowding is severe; when it passes 5000 the overcrowding becomes extreme. As this happens the meningococcus carrier-rate rises and when the latter passes the danger line of 20 per cent. cases of cerebro-spinal fever occur. Cases of rheumatic fever occur at the same time and in almost equal number, suggesting that a similar process is at work. The shaded area shows a short period of intense overcrowding following the great call up of April, 1918. It is cut short by special measures. "Spacing out" (i.e., increasing the distance between beds to 2½ ft. and improving ventilation) from October to April, produces almost complete cessation of cases of both diseases, even in their epidemic season, and the carrier-rate falls to nil.

---

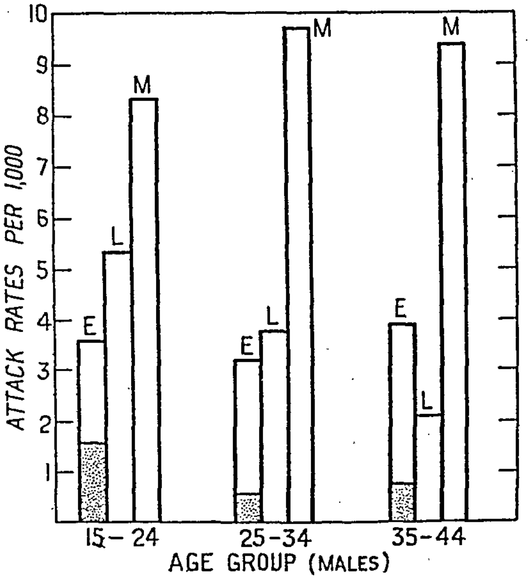
† Compton has shown how a damp atmosphere may facilitate droplet infection.

once the infection has taken place, acute rheumatism assumes the form of a *chronic infection*, which may have long periods of latency, alternating with periods of activity and advance.

STATISTICS FROM HOSPITAL.

Statistics based on hospital admissions for acute rheumatism confirm the impression of a declining incidence, for the proportion of admissions of patients with acute rheumatism to the proportion of all medical in-patients has been steadily diminishing since about 1895. Ormerod,[23] in 1852, stated that 11·2 per cent. of all admissions to London hospitals were on account of rheumatic fever. Miller,[24] taking quinquennial periods from 1869–1914, from the St. Bartholomew's Hospital Reports, showed that the proportion of acute rheumatic cases to all medical in-patients had dropped from about 10 to about 5 per cent., the percentage of acute rheumatic patients who developed pericarditis had also fallen. Since the war the diminution in London has been rapid.

FIG. 6.



Attack-rate of acute rheumatism for various age-groups in England during 1922 (E), in Leipzig[22] 1887–1907 (L), and in Moscow during 1928 (M). The stippled areas in the English columns represent "acute" as opposed to "subacute" cases. Moscow age-groups are 15–19, 20–29, 30–39.

Dr. A. A. Osman and Dr. H. G. Close have kindly put at my disposal the figures for Guy's Hospital and Lambeth Infirmary, which show (Fig. 7) that the annual admissions for acute rheumatism at Guy's Hospital during the five years 1910–14 averaged 148, the average number of medical in-patients per year being 2746, a percentage of 5·4, nearly identical, that is, with the St. Bartholomew's figures for 1914. For the six years 1921–26 the average number of admissions is 26 on an average total number of medical in-patients of 2266, a percentage of only 1·1, one-fifth that is of the previous proportion.

At the Lambeth Infirmary for the four years 1911–15 acute rheumatism furnished 1 per cent. of the total number, whilst for the six years 1922–27 the proportion was only 0·45 of the total number of admissions. The Royal Free Hospital in 1928 admitted 1·47 per cent. of all in-patients on account of acute rheumatism. The late Dr. Wheatley, of Shropshire, pointed out that at Blackburn Infirmary in the years 1888, 1889, and 1890, no less than 100 cases of rheumatic fever, mostly of a severe type, were admitted, whereas during 1920, 1921, and 1922, only 11 cases were admitted.

In America, Lambert,[25] at Belle Vue Hospital, New York, in 1920, found that there had been a striking diminution, especially marked in persons between the ages of 20 and 29, although the number of admissions in the 5 to 9 group had increased, whilst the 10 to 14 group was practically stationary, and the 15–19 group had decreased slightly, but not in proportion to the diminution for all ages. D. and B. C. Seegal[26] have studied hospital admissions in the United States and Canada, and point out that the average annual frequency has diminished, though not uniformly, for in 1924 and 1925 certain hospitals, such as the Presbyterian Hospital, New York, and the Johns Hopkins Hospital, Baltimore, showed an increased rate of rheumatic fever admissions. The disease, however, now seems more typical, severe, and frequent in the North Eastern States and in Canada than in this country. Dr. C. P. Howard,[27] of Montreal, says: "The picture of rheumatic fever that we see in Montreal impresses one with the frequency and severity of the disease. In the Montreal General Hospital of 5000 patients admitted to the wards, 226 (4·5 per cent.) had rheumatic fever. Both sexes suffer equally, and the age of greatest incidence comprises the second, third, and fourth decades." This was the state of things in London 35 or 40 years ago.

Children's hospitals in London naturally show a higher ratio of admissions. Gordon Pugh[28] in 1925 found in six London children's hospitals 377 in-patients out of 10,096 suffered from acute rheumatism or its effects—3·7 per cent. Ninety-nine only of the 377 were cases of rheumatic fever, 117 were cases of carditis, and 161 had chorea.

AN OBSOLESCENT DISEASE?

Our review of the incidence of acute rheumatism seems to show that it, like tuberculosis, is slowly but surely being conquered. But the analogy with scarlet fever must make us cautious lest another wave of increased virulence (such as that culminating in 1875 in scarlet fever) occur in acute rheumatism, and so falsify our optimism. We seem, however, to be seeing the same process of epidemiological obsolescence in acute rheumatism that Creighton saw in small-pox. "It would," he said, "be a not incorrect summary of the incidence of small-pox in Britain to say that it first left the richer classes, then it left the villages, then it left the provincial towns to centre itself in the capital; at the same time it was leaving the age of infancy and childhood. Of course, it did none of these things absolutely."

Acute rheumatism seems to be following this course, but it certainly has not yet left the age of childhood. But whilst we appreciate this cheering decline in the incidence of rheumatic fever, we are still painfully aware of the high incidence in children of the major or minor stigmata of the acute rheumatic infection, and of those many patients who, in what should be their happy youth or vigorous manhood perish slowly of rheumatic heart disease.

The triumph over acute rheumatism, of which this decline is but the herald, is yet afar off. It must but spur us to further effort, first to prevent as far as possible the infection of children, secondly to supervise those who may have been infected, thirdly to provide institutional treatment suitable for those seriously infected to ensure them the fairest chance of recovering from their carditis without permanent damage to the heart.

First, can infection be prevented? Every slum destroyed, every overcrowded tenement cleared, every unhygienic school building improved, every playing field provided, is a step forward. Education of parents and children as to nurture, diet, and fresh air are of great importance, and every improvement in food, wages, hours of work, and sobriety helps to raise the resistance of the child of the industrial town against the infection of acute rheumatism.

The school medical service has already accomplished great things; the children are hardly recognisable as the same class so much have they altered for the better in the 21 years since I was a school doctor in public elementary schools. For the supervision of those who may be infected, in large towns the rheumatism supervisory centre appears indispensable; it does best when attached to a children's hospital, the officer in charge should be a physician of consultant standing, used to children, and of winning personality. London now has 11 of these centres. As regards institutional treatment, I here should like to pay tribute to the pioneer work of the Invalid Children's Aid Association in providing London with the first two residential schools specially for children convalescent from rheumatic heart disease. When in this coming autumn the Metropolitan Asylums Board add to the 170 beds they already provide for rheumatic children the new accommodation of 350 beds they are adding for this purpose to Queen Mary's Hospital, Carshalton, London will have a provision of this special accommodation equal to that of any city in the world.

FIG. 7.

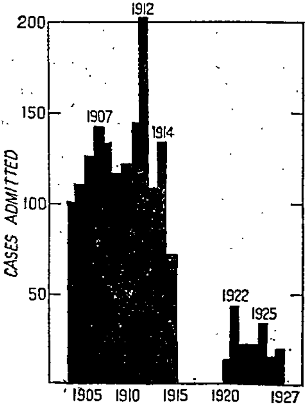


Diagram showing cases of acute rheumatism (actual numbers) admitted to Guy's Hospital in the years 1905–15 and 1920–27. (Drs. Osman and Close.)

If in this lecture I have omitted many aspects of the incidence, it is because my first task seemed to be to restate the incidence of acute rheumatism (notwithstanding its low infectivity) as the incidence of a specific infectious disease conveyed by droplet infection.

THE QUALITATIVE SERUM DIAGNOSIS OF ENTERIC FEVERS.

DIRECTIONS FOR ITS PERFORMANCE.

BY A. FELIX, D.SC. VIENNA.

(From the Bacteriological Department, Lister Institute, London.)

IN a recent editorial article in THE LANCET[1] the reasons for failure of the Widal test performed by the customary quantitative method have been discussed, and attention has been drawn to the qualitative method which I have suggested for the serological diagnosis of enteric fevers.[2] This method has been alluded to as "somewhat of a mystery." While this statement does not appear to be justifiable, it must be admitted that the new method is unknown to clinical pathologists, and has—with few exceptions only (Stuart and Krikorian,[3] Gardner,[4] Pijper[5])—not been subjected to a serious critical test. A brief account of this qualitative method, including technical directions for its performance, may, therefore, be of some interest.

The principles of qualitative serum analysis have been derived from the study by Weil and Felix[6] of the antigenic structure of *Bacillus proteus* and the typhoid-paratyphoid group of organisms. These and other flagellated bacteria possess the two kinds of antigen known as the "O" and the "H." The present knowledge of the occurrence of these two kinds of antigen, their immunological significance, and their inter-relationship among the various members of the salmonella group has been given a lucid presentation by Topley and Wilson[7] in their recently published text-book, to which the reader is referred.

The qualitative method of diagnosing enteric fevers is based on the distinction of "O" and "H" agglutinins in the patient's serum. For the sake of simplicity, typhoid and paratyphoid A and B only are dealt with in the following account of the procedure. Infections due to other members of the salmonella group of organisms—e.g., *B. paratyphosus* C, *B. enteritidis Gaertner*, *B. aertrycke*, &c., are excluded here from consideration.

Technique.

The macroscopic technique only is to be applied. For well-equipped laboratories the use of suspensions of living bacteria is still recommended since they give the highest degree of sensitiveness. Where a well-equipped laboratory is not available, properly prepared preserved suspensions should be employed.

(a) *Suspensions of living bacteria.*—Fresh saline suspensions of living bacteria from 24 hours old agar slopes are used. Certain details of the preparation of the agar medium must be strictly observed (see Felix,[2] Stuart and Krikorian[3]).

Although the differentiation between "H" and "O" agglutination can be made with any laboratory strain since their characteristics are sufficiently distinct and constant, still it is recommended to use the following strains, whose known antigenic properties and sensitiveness to "O" agglutinins are of assistance to this differentiation.

"H" 901 =	*B. typhosus*	= "H" variant of strain 901 (Weil and Felix).
"O" 901 =		= "O" variant of strain 901 (Felix and Olitzki).
"H" B2 =	*B. paratyphosus* B	= "H" variant of strain No. 2.
"O" B =	*B. aertrycke* ..	= "O" variant of strain "Glasgow" (Schütze).
"H" A6 =	*B. paratyphosus* A	= "H" variant of strain. No. 6.
"H" A1 =		No. 1.

It will be seen that six cultures are used for the differentiation of "H" and "O" agglutinins in cases of the three most common enteric infections, those due to *B. typhosus* and *B. paratyphosus* A and B.

If one used “O” and “H” variants of these three organisms for the detection of the three pairs of “O” and “H” agglutinins, the “O” variant would serve as reagent for the corresponding “O” agglutinin only, whereas the “H” variant, which reacts to both kinds of antibody, would detect the “H” agglutinin. However, a true permanent “O” variant has up till now only been isolated in the case of *B. typhosus*; an “O” variant of *B. aertrycke*, recently isolated by Schütze,[10] has been selected as the reagent for “O” agglutinins of *B. paratyphosus* B, since these two organisms possess identical “O” antigen; in the case of *B. paratyphosus* A, since a pure “O” variant is still lacking, a strain A1, which is sensitive to “O” agglutinins as well as to “H” must be substituted. Another strain A6, which is equally sensitive to “H” but not to “O” agglutinins, can conveniently be used in addition for comparison.

All these cultures are in the National Collection of Type Cultures. With the exception of the recently isolated “O” variant of *B. aertrycke*, all of them have been used in agglutination tests for many years. The strain *B. typhosus* 901 has constantly retained its remarkable sensitiveness to “O” agglutinins for a period of 12 years.

Both the “H” and “O” variants should be tested from time to time with appropriate rabbit immune sera in order to ascertain whether their respective antigenic properties have been maintained. Such controls are essential since $H \rightleftarrows O$ variation is reversible. Especial attention must also be paid to the smooth-rough variation of the cultures used (Arkwright[8]); saline controls of all bacterial suspensions with solutions of 3·4 per cent. and 6·8 per cent. NaCl should therefore be added to the customary control with normal saline. Andrewes's group-type phases, concerning the “H” antigen of *B. paratyphosus* B, cannot be discussed here.

Two dilutions of the patient's serum—viz., 1 in 100 and 1 in 200, are tested with each suspension; the second dilution is included only as a safeguard against the chance error inherent in a single tube method. Titration to the titre limit is unnecessary for routine diagnosis, with the exception of those cases which have a history of a previous enteric infection (see last section, 3 *c*). However, titration to the end-titre is of assistance in differentiating between “O” and “H” agglutination, until certain initial difficulties in reading the results have been overcome by experience. Moreover, the titre limit of “O” agglutinins has a definite prognostic significance.[2]

The results are read with a lens of about 10 X magnification after incubation for two hours at 37° C., and again after further 16–18 hours at room temperature.

(*b*) *Preserved suspensions.*—(1) Suspensions of “H” variants preserved in the usual way with phenol or formalin are sensitive reagents for “H” agglutinins, but may react also slightly with “O” agglutinins. (2) Alcohol suspensions of both “O” and “H” variants are pure reagents for “O” agglutinins, but not so sensitive as living cultures.

Alcoholic suspensions of the sensitive strain *B. typhosus* 901 have already been prepared by Dr. Gardner[4] (Oxford), who recommends 24 hours incubation at 52° C. for this suspension. It is hoped that separate suspensions for demonstrating “H” agglutinins alone will eventually be available in addition to the alcohol suspensions which are pure reagents for “O” agglutinins. These might be obtained by selecting “H” variants of strains of very low sensitiveness to “O” agglutinins and by increasing the concentration of phenol or formalin until the inhibitive action of these chemicals on “O” agglutination (Felix and Olitzki[9]) completely suppresses the “O” agglutination in these suspensions. Thus preserved suspensions of such high and permanent sensitiveness will be obtained that they can be substituted for the suspensions of living cultures whose inherent disadvantages are well known.

Differentiation of “O” and “H” Agglutination.

“H” Agglutination.	“O” Agglutination.
Forms rapidly.	Forms slowly.
Settles rapidly.	Settles slowly.
Flakes large and of varying size.	Flakes small and uniform.
Sediment voluminous.	Sediment scanty.
Supernatant fluid turbid.	Supernatant fluid clear.
Sediment easily dislodged (becomes similar to saline control on shaking).	Sediment difficult to dislodge (cuticular floating in clear fluid).

The decision as to whether “H” agglutinins are present or not (alone or simultaneously with “O” agglutinins) is in the majority of cases made by reading after two hours. This decision can often be made earlier; repeated inspection of the tubes in the course of the first two hours is therefore advisable. The second reading, after 18 till 20 hours, discloses weak “O” agglutination in those cases in which it was still invisible after two hours.

When suspensions of living bacteria are used, attention must be paid to the fact that the reaction of the “O” agglutinin occurs much more slowly with the “O” variant than with the “H” variant, although the degree of agglutination seen after standing all night is, as a rule, distinctly higher with the “O” than with the “H” variant.

Interpretation of Results.

General remark.—In “H” agglutination even a weak reaction in a serum dilution of 1 : 100, corresponding to + or ± may be considered as “positive.” “H” agglutinins do not occur in human normal serum, certainly not in a dilution of 1 in 100. In “O” agglutination, however, only a strong reaction should be considered as “positive,” since normal agglutinins in human serum are “O” agglutinins, and may even reach a titre of 1 in 100. This is especially the case with the sensitive strain *B. typhosus* 901 (cultures “O” 901 and “H” 901), and only a result 1 in 100 + + + shall be taken as “positive.” Weaker reactions shall be designated as “doubtful.”

1. *In cases not previously inoculated and not giving a history of previous enteric infection.*—(*a*) “H” agglutination with one of the strains used definitely decides the diagnosis. “H” agglutination can occur with the homologous organism only—i.e., that responsible for the infection. (It is pointed out again that cases of infection with *B. paratyphosus* C, *B. aertrycke*, &c., are not here considered.) (*b*) “O” agglutination with one or two or with all strains definitely gives only the diagnosis “enteric group.” The differentiation between typhoid and paratyphoid A and B cannot be reached from “O” agglutination; titration to the end-titre is of no assistance to this differential diagnosis. (*c*) In typhoid fever as well as in paratyphoid A and B infections, “O” agglutination usually occurs earlier with the sensitive cultures “H” 901 and “O” 901 than with the homologous strains. This, together with the fact that “O” agglutinins appear in the patient's serum at an earlier date than “H” agglutinins, renders early serological diagnosis possible.

2. *In the inoculated* (without regard to the time that has elapsed since inoculation).—(*a*) In patients inoculated with the polyvalent TAB. vaccine, “H” agglutination must be entirely disregarded. (*b*) In patients inoculated with monovalent T. vaccine, the “H” agglutination with A or B is as significant as in the uninoculated and “H” agglutination with T. only need be disregarded. (*c*) “O” agglutination with either of the strains gives the diagnosis “enteric group”; further differentiation within the group is not possible by serological examination.

3. *In cases which have a history of previous enteric infection* (without regard to the time that has elapsed since that infection).—(*a*) If the type of the previous infection is precisely known (T.A. or B.), the appearance of “H” agglutinins for another type definitely decides the diagnosis. (*b*) If the type of

the previous infection is unknown, "H" agglutination must be entirely disregarded. (c) Residual "O" agglutinins show significant fluctuation of the titre only in the course of another enteric infection. The appearance of "O" agglutinins or a marked fluctuation of their titre are, therefore, of diagnostic significance, and justify the diagnosis "enteric group." For this particular purpose the "O" agglutinins must be titrated up to the end-titre.

TWO PITUITARY TUMOURS.

BY A. L. TAYLOR, B.Sc., M.B., F.R.C.P. EDIN.,

SENIOR ASSISTANT, STAFFORDSHIRE MENTAL HOSPITAL, BURNTWOOD.

THE two cases of pituitary disease which form the subject of the following observations occurred in mental hospital patients, one in 1912 and the other in 1928. Though differing widely in their clinical course and pathology, both cases present unusual and, I venture to state, unique features.

The first case was published in 1913 by the courtesy of Dr. S. Rutherford Macphail, then superintendent of the Derby Borough Mental Hospital. I have to thank Dr. William Reid, superintendent of the Staffordshire Mental Hospital at Burntwood, for his kind permission to use the second case for this paper.

The Cases Described.

CASE 1, a married woman of over 40 years of age, first came under observation in 1908 on account of mental symptoms. At first these consisted of apathy, with loss of memory and emotional reaction. An ophthalmoscopic examination at this time revealed nothing abnormal, and there was no complaint of headache or vomiting; the mental state would not allow a test of the fields of vision. Frequent incontinence of urine and fæces was present, due probably to mental indifference. In December, 1908, she was sent to the Derby County Asylum, and while there the mental apathy became more profound. In April, 1909, she was tried at home again but did not improve and had several fits indistinguishable from ordinary epileptic seizures. All this time she took her food well but remained totally indifferent to everything else, being very somnolent and staying in bed all day. She was readmitted to the Derby County Asylum in October, 1911, and transferred to the Borough Asylum in December. On admission to the Derby Borough Asylum she was a woman aged 48, of middle height, dark complexion, and satisfactory general nutrition; the hands and feet were small and well-formed. Physical examination revealed a mitral presystolic murmur, somewhat myotic pupils with a sluggish light reaction, dull flexor plantar reflexes, ordinary knee-jerks, and no diminution of the pain sense so far as could be made out. The urine, beyond being rather concentrated, showed no abnormal features. The mental condition was one of apathetic dementia with inability to answer any but the very simplest questions, and complete indifference to the passage of the evacuations. She complained of no pain. She resented greatly any attempt to examine the eyes, so that ophthalmoscopy was not possible, but she certainly suffered from marked dimness of vision, as evinced by her manner of eating and going about. This became more pronounced from month to month. On her admission there was no physical sign of paralysis or paresis, and she was able to walk quite well. Her mental symptoms became more accentuated, and in March and April, 1912, she had two fits with bilateral convulsions. About this time weakness of the right hand showed itself and she also had several mild attacks of painless vomiting. On June 1st, 1912, she was noticed to become more drowsy than usual, and in the evening passed into a series of fits, 15 of which succeeded one another without return of consciousness. She remained comatose with very stertorous breathing, and died in the middle of the following day.

Necropsy.—On removing the calvarium, which was markedly increased in thickness and density, especially in the frontal region, the following evidence of extreme cerebral compression was noted: the dura was very tense, the subdural space was practically obliterated, and the superficial convolutions were quite flattened. On removing the brain, an ovoid tumour was seen in the centre of the anterior cranial fossa; it measured 4·5 cm. transversely and 6 cm. anteroposteriorly, and was firmly attached to the sella turcica and less so to the cribriform plate of the ethmoid. The surface was nodular and the consistence firm, the growth being quite circumscribed and only exerting pressure on the adjacent parts. A deep hollow was thus present in the base of the brain, extending from the posterior perforated spot to the frontal pole, and being widest midway between those two points. The floor of the hollow consisted of the flattened convolutions of the mesial and inferior surfaces of the frontal lobes, the encroachment being slightly more extensive on the left side than on the right. The optic chiasma and the olfactory tracts and lobes were not distinguishable. Sections of the hardened brain showed that the cavities of the lateral and third ventricles were almost absent; the brain was otherwise healthy to the naked eye and weighed 41½ oz. The tumour was examined microscopically by the late Dr. W. Ford Robertson and was described as a spindle-celled sarcoma; but I am now inclined to think that it belongs to the endothelioma class; at any rate, there is no doubt that it was a non-malignant connective tissue tumour.

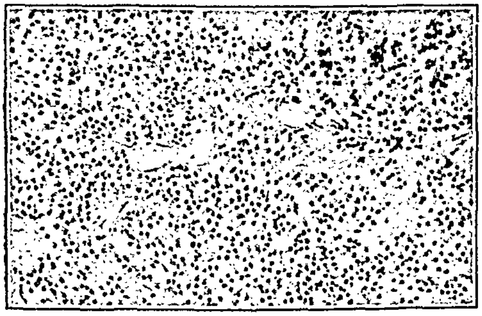
CASE 2, a single female, aged 67 years, was admitted to the Burntwood Mental Hospital on April 25th, 1928. Before admission she had been restless and unreasonable in conduct for several weeks. She was said to have had a fall in the house two years previously and not to have been the same since then. She had been more or less confined to bed for 18 months owing to an affection of the knees. The family history showed that brothers and sisters had died of cancer, tuberculosis, and pneumonia. The causes of her parents' deaths were unknown and no mental disease had been heard of in the family. She was at first sent to the poor-law hospital at West Bromwich, but proved so difficult to manage that she was transferred to the mental hospital: she was confused and restless and gave evidence of visual hallucinations. She was of average nutrition and rather flabby; her height was 5 ft. 1 in., and her weight 9 st. 2 lb. There was no deformity of the hands but severe chronic arthritis of both knees with bony thickening at the margins of the articular surfaces of femora and tibiæ and permanent flexion of both joints; she complained of pain on passive movement of the knees. The skin was clear and not abnormal; the hair was dark. She had no teeth. Her arteries were thickened moderately and her heart's action weak, but there were no signs of valvular disease. The urine showed no abnormalities. The tongue was coated. Nothing abnormal was observed in the nervous system; her vision seemed acute, the pupils were normal, and she was not deaf. There was nothing unusual in the face. She was confused, stupid, and emotional; had no proper appreciation of time or place and had well-marked loss of memory for recent events. Her general conduct was childish and querulous but not unusually restless. In other words, the mental picture was one of senile dementia (cerebral arteriosclerosis), and this was supported by the patient's physical state.

For about four months the mental and bodily condition remained much the same. The only additional facts noted were that she often had incontinence of urine but that the quantity passed always seemed to be normal; she occasionally expressed delusions based on visual hallucinations—e.g., she would complain that strange men visited the ward at night. She took her food well and showed no mental torpor or drowsiness; in fact, she was quite alert in many respects. On the whole she was the kind of case which, were it not for incontinence of urine, would probably have remained in the poor-law hospital. At the beginning of October, 1928, it was practically arranged that she should be nursed at home. On Oct. 16th there was quite a sudden change. She became less alert mentally, with distinct drowsiness and disinclination for food, and had some œdema of the right naso-orbital part of the face. The pupils were normal and no ophthalmoplegia could be made out; owing to her great resistiveness the ophthalmoscope could not be used. Next day the drowsiness and œdema had increased; she had to be spoon-fed with fluids, and had retention of urine. A catheter specimen of urine showed nothing abnormal. The next day the œdema was present on both sides of the bridge of the nose and she was semi-comatose. In the last days of the illness the only definite paralytic sign was paresis of the right lower face on Oct. 19th; by this time she could not speak, but owing to her semi-conscious state, this was not necessarily caused by a focal lesion. The movements of the upper limbs remained normal and there was no change in the lower extremities. The coma increased and swallowing became more and more difficult, and she died on Oct. 21st.

Necropsy.—The contraction of the lower limbs caused by the chronic arthritis was the only external evidence of disease. On opening the cranial cavity evidence of cerebral compression appeared in diminution of the subdural space and cerebro-spinal fluid and some flattening of the lateral convolutions. A tumour in the pituitary region was discovered, resembling a good-sized damson in size and shape, with the long axis transverse; a thin shell of separated bone was to be seen on the posterior part of the upper surface, this evidently being the attenuated posterior wall of the sella turcica. The growth was extremely soft and succulent in consistency, so much so that the violence of chiselling the cranial base caused a fissure in its surface. The cup-shaped depression produced was bounded posteriorly by the anterior aspect of the mesencephalon, the corpora mammillaria being flattened on either side by the mesial aspects of the temporo-sphenoidal lobes and in front by a transverse line passing between the poles of the temporo-sphenoidal lobes in front of the posterior fourth of the gyri recti in the frontal lobes. The growth had passed neither in front of nor behind the optic chiasma but had displaced this structure vertically upwards. The third nerves must also have been stretched by the growth. A sagittal mesial section through the growth and its place of origin does not show any encroachment on the sphenoidal sinus and also demonstrates the absence of the posterior wall of the sella.

The tumour was kindly examined by Dr. W. F. Harvey, histologist at the laboratory of the Royal College of Physicians of Edinburgh. Two photomicrographs were taken (Figs. 1 and 2). The stroma was found to consist of columns of cells arranged in whorls and curves; in some parts supporting trabeculæ of a rudimentary appearance were present, and there were numerous capillary blood-vessels. Nearly all the cells were definitely glandular in type, showing either clear protoplasm or a varying degree of granularity, the granules being refractile in appearance and not having a marked affinity for the acid stain. The nuclei of these cells were large, oval in shape, and contained a very well-marked basophile network. Besides the large glandular cells there were a few lymphocyte-like elements with round, deeply staining nuclei and scanty, clear cytoplasm. No mitotic figures were to be seen, but there were some bizarre types of nuclei which are said [1] to be often seen in rapidly progressing hyperplasias of this kind. No spaces containing colloid material were to be seen. It was concluded that the tumour was an adenoma of the anterior lobe of the pituitary gland. The posterior lobe of the gland was presumably flattened and compressed, but a microscopic section was not made to demonstrate this point.

FIG. 1 (Case 2).



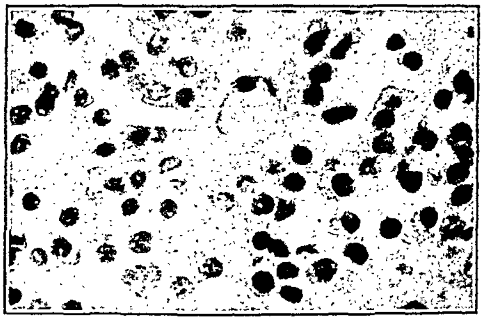
Section of pituitary adenoma (low power).

The brain showed the appearances which would be expected in a case of not very severe senile dementia—viz., some thickening and milkiness of the pia arachnoid over the cerebral convexity, pallor of the cerebral cortex, and marked sclerosis of the intracranial arteries (the thickened basilar artery was conspicuous). The slight increase in the subdural space usual in such cases was not noticeable, perhaps owing to the neoplasm. There was mitral stenosis of moderate degree with some cardiac hypertrophy and moderate chronic venous congestion of the liver and spleen; the suprarenal glands appeared perfectly normal to the naked eye. General arterio-sclerosis with some aortic atheroma was present.

Remarks.

Clinical Course.—There is nothing exceptional in the clinical course of Case 1. The duration and gradual development of the symptoms and signs were similar in character to those of many other intracranial growths. Cushing's Case 8 [2] was very similar in many ways, was described as a most unusual case (infundibular endothelioma), lasted five years, and died after surgical treatment. In Case 2 the course of the illness is remarkable for its extremely short duration. The actual date of commencement of symptoms due to the pituitary growth is difficult to settle owing to the concomitant senile dementia, but pressure effects did not appear until little more than a week before the patient's death, and their character suggested unusually rapid growth. I can find no record of any actual pituitary growth announcing itself with such dramatic suddenness. The patient never even complained of headache (she certainly would have, had it occurred) and showed no drowsiness until about a week before her death.

FIG. 2 (Case 2).



Section of pituitary adenoma (high power).

Pressure effects caused by pituitary growths are variable,[3] but depend on the speed and duration of the growth. Apart from symptoms common to all cerebral tumours, one may note especially bi-temporal headache, sleepiness passing into stupor, and the changes in vision due to pressure on the optic tracts, chiasma, and nerves. As a rule, the pituitary tumour bulges upwards in front of the optic chiasma, and the result is the classical bitemporal hemianopsia.[4] Rarely, as in Case 2, the nerves and chiasma are pushed vertically upwards and are thus compressed between the tumour and the circle of Willis; the result will be papillœdema, with loss of vision later on. Under such circumstances it is obvious that the differentiation of the pituitary growth from an intracranial tumour elsewhere may be difficult, as a large tumour may, by pressure, cause signs of hypopituitarism. In Case 2 there was œdema on either side of the bridge of the nose; this commenced just after the onset of the drowsiness. I am unable to find a record of this sign in connexion with enlargements of the hypophysis; it is not alluded to by Cushing, Berkeley, or Walton, and the first-named of these authorities collected a relatively vast number of cases and studied them in the greatest possible detail. It is obvious that the œdema is caused by pressure on both cavernous sinuses or, more probably, directly on the ophthalmic veins, which have the angular vein as one of their tributaries.[5] Walton refers to pressure on the cavernous sinus as causing trigeminal neuralgia. The sudden interference with the local circulation can only be accounted for by some equally uncommon cause, and therefore one may infer that the speed of growth of the tumour was quite exceptionally rapid. Diplopia has been noted occasionally in such cases; it is conceivable in Case 2, where the oculomotor nerves were unquestionably on the stretch, that the visual hallucinations may have had diplopia as their sensory basis.

Epileptic fits occurred in Case 1, and, indeed, were the cause of death. There has been divergent opinion on the relationship of the pituitary to convulsive attacks and other fits. Cushing[6] assembles the data bearing on this matter in what would appear to be rather a convincing argument in favour of pituitary deficiency as a likely cause of idiopathic epilepsy. It must be admitted that many cases of hypopituitarism have shown epilepsy, and that many epileptics exhibit adiposity and a high sugar tolerance; but also that hypopituitarism of the most severe type may be unaccompanied by fits and that many epileptics are far from being obese. To extend the argument, one may instance the following almost commonplace facts: many cases of epilepsy are found post mortem to be associated with definite varieties of increased intracranial pressure, while the majority show no such condition; one case of general paralysis of the insane may show convulsive seizures while another of very similar course and pathology never has any; the same degree of uræmia (as far as comparisons are possible) may produce fits in one subject but not in another. An Italian physician[7] recorded a case in 1909 very similar to Case 1, quâ anatomy and symptoms, except that there was no epilepsy. I am, therefore, inclined to regard the epilepsy in Case 1 as having been due (in a predisposed subject) to the general pressure on the cerebrum rather than to hypopituitarism caused by pressure on the gland. Pituitary therapy for epilepsy was given an extensive trial in the United States over ten years ago,[8] but "has now died a natural death, though some of the manufacturers have tried to galvanise the corpse." In the latest published work by a physiologist on the pituitary, Sharpey-Schäfer's "Endocrine Organs," there is no indication that the relationship of the pituitary to epilepsy is to be taken seriously.

The *general effects*—viz., those due to interference with the normal function of the gland—are conspicuous by their almost complete absence. In Case 1 the mental torpor might be due to the pressure on the frontal lobes just as well as to pressure on the pituitary and, moreover, the absence of adiposity or anything suggesting Fröhlich's syndrome would make the former alternative more probable. In Case 2 there were, on the one hand, no signs of acromegaly or glycosuria and, on the other hand, no sign of increased carbohydrate tolerance or of polyuria. For over five months after admission to hospital no abnormal drowsiness occurred, there was no headache, and the patient was far from being indifferent to her surroundings. The drowsiness which ushered in the end of the illness was certainly very marked, and I am inclined to ascribe this symptom, in part at least, to pressure on the posterior lobe of the gland.

Pathology.—The normal anterior lobe of the human pituitary gland is composed of columns of cells surrounded by large sinusoidal spaces.[9] The cells are of three types: eosinophile, basophile, and neutrophile. *The basophile cells are not numerous.* The eosinophile cells are typical gland cells, and the presence of the granules indicates active secretion. Much experimental blood has been spilt in discussion as to whether these cells actually represent different types or merely different states of the same kind of cell. Many variations are noticed in normal glands as well as in pathological states. The actual histology of the normal gland (anterior lobe) and of adenomata arising from it suggests that, at any rate, the neutrophile and acidophile cells are different states of the same kind of cell; various grades of acid affinity are easily recognised. Even in the sections of the adenoma from Case 2 (Figs. 1 and 2), though the cells are neutrophile, yet they show a faint eosin stain, and in some cases a distinct, though faint, granular appearance. Acromegaly is produced by hypersecretion of the anterior lobe, but as hypersecretion and hyperplasia of a gland—e.g., the thyroid—are by no means synonymous, it follows that many cases of adenoma of the anterior lobe will never have acromegaly, but will show varying degrees of hypopituitarism caused by pressure on the posterior lobe. Also, the majority of cases of acromegaly show hypopituitarism in their later stages, and in such cases a chromophobe adenoma is found. Cushing's Case 1 is a typical example.[10] In our Case 2 actively secreting cells were not seen in the adenoma, and we are therefore not surprised that there were no signs of acromegaly. Had the growth not been so rapid we should have expected more definite signs of posterior lobe deficiency at a later period of the illness.

Case 1 is interesting mainly on account of its extreme rarity. An endothelioma of the infundibulum is a variety of sarcoma, and parts of it may resemble a spindle-celled sarcoma. Although Case 1 is described as a spindle-celled sarcoma, it probably has much the same cellular origin as the endothelioma; neither can honestly be described as malignant. The case described by Sandri,[7] which clinically resembled Case 1 so closely, was a round-celled sarcoma. Most frankly malignant growths in this region invade the base of the skull, and may reach the nose and nasopharynx.

TREATMENT OF "TENNIS ELBOW."

WITH SOME OBSERVATIONS ON JOINT MANIPULATION.

BY THOMAS MARLIN, M.D. GLASG.,
D.P.H., D.M.R.E.,

MEDICAL OFFICER IN CHARGE OF THE MASSAGE AND ELECTRO-THERAPEUTIC DEPARTMENTS, UNIVERSITY COLLEGE HOSPITAL.

THE point of view from which I propose to review this subject is that of the physiotherapist. It goes without saying that medicines and liniments have failed and the bone-setter has scored. The treatment therefore lies within the domain of physiotherapy and orthopædics, but my object is to discuss what can be done short of surgical interference.

Although the term tennis elbow is a misnomer, it is probably convenient to retain it, as it refers to a condition of pain or disability induced when the gripping muscles are brought into action. The pain is generally situated somewhere round the radiohumeral joint or in the extensor muscles of the wrist and hand near their origin. There may, however, be pain located near the inner aspect of the elbow. The condition occurs in golfers, usually through taking too much turf on hard or frosty ground, and twice I have seen it bilateral. It may occur from carpentry, sawing, and planing. I have seen it in a draper's assistant who did no more strenuous exercise than play skittles, but on the other hand motor mechanics doing very heavy work may acquire the same symptoms; one of my last patients was a man who amused himself by bending 6-inch wire nails between his hands. Writer's cramp would almost seem to fall into the same category, as I have occasionally seen this respond to some of the treatment described later. It has been suggested that only amateur tennis players get "tennis elbow," the professional players knowing better how to hold their racquets, but I have seen several Wimbledon competitors and at least one finalist who had the complaint, and the assumption is that men of that class would know how to grip their racquets.

Diagnosis.

Short of cutting into the joint as W. H. Trethowan has done, we have nothing positive to go on.

X rays give no help, so we are led to the assumption of strains, neuritis, effusions of one sort or another, or slight arthritis; the only positive thing is the exact location of the pain, and even that may vary during treatment. It is an essential of good practice that diagnosis should precede treatment, but considering the difficulty of exact diagnosis and bearing in mind many cases treated successfully, the question arises whether part of the diagnosis might not be deduced from a consideration of the results of different forms of treatment, together with some points in the location of the pain.

From the point of view of diagnosis, the chief things which the examiner may elicit, apart from the general indefinite pain in the muscles, are: (1) pain on pressure over the outer aspect of the radio-humeral joint; (2) pain on deep palpation over the anterior aspect of the same joint; (3) pain on pressure over the tendon of the long head of the biceps, a point to which I have never seen reference made; (4) occasionally pain on pressure over the front of the wrist, between the radius and ulna; (5) constriction applied round the upper part of the forearm reduces the pain of gripping.

In my experience there is no treatment so successful as manipulation of the elbow-joint. If that is so, we are bound to ask ourselves whether there may not be some subluxation, rotation, lesion, fixation (or anything else we may term it) in the joint. Why is there pain on pressure over the front of the joint as well as over the long head of the biceps? Suppose the joint has been jarred, is it possible that the head of the radius can remain twisted, even though anatomically it may seem improbable? Should that happen, there would also be a rotation of the bicipital tuberosity of the radius leading to a torsion of the biceps. That torsion would necessarily be very slight, but might account for the pain. The mechanics of the body are very wonderful, the different fibres of muscle tendon and ligament are arranged in certain directions for special purposes, just as lines of stress are arranged very methodically in the bones, and at present we are unable to say just how far small deviations from the normal may affect the health of the part. Likewise the joint interference may react on any of the surrounding tissues. Neuritis or slight arthritis may set in, but at any rate the muscles develop spasm and will not relax properly, with the result that a certain awkwardness of movement, want of coördination, or interference with proper synergic action takes place.

Treatment.

No one form of treatment is sufficient for all cases that present themselves, but I have now managed to arrange the different treatments in the best order with regard to probability of success and feasibility of application without undue waste of time: (1) manipulate the joint to ensure perfect alignment of the bones; (2) encourage the muscles to relax; (3) treat any remaining pain by the different electrical methods—diathermy, ionisation, light therapy, faradism, galvanic acupuncture; (4) massage.

The specific manipulation having been effected, the muscles should be coaxed into a condition of relaxation and freedom of action. Given a little encouragement, things tend to right themselves, and sometimes I allow the patient to play straight away just as he feels inclined. Generally speaking, games or any natural effort are better than particular exercises. In the latter case the mind is apt to concentrate too much on the affected muscles and keep up the spasm, whereas in the enjoyment of the game and the heat of the contest the muscles, so to speak, forget themselves. They suddenly begin to act in a normal loose manner and tend to lose their spasm, and once that happens they go on getting more supple.

Strapping the forearm, as advised by Frank Romer, is a very powerful aid at this stage of the treatment. Three pieces of strapping about 1¼ inches wide are cut long enough to encircle the upper third of the forearm with a slight overlap. They are applied upwards from the lower part of the upper third of the forearm, each succeeding piece slightly overlapping the previous one, care being taken to avoid creases. The last piece of strapping has a piece cut out of it to allow bending at the elbow. During the application of the strapping the patient keeps the elbow bent and the wrist and fingers flexed and pronated. It is not necessary to apply the strapping tightly, because when the patient dorsiflexes the wrist and clenches the fingers the circumference of the forearm increases; hence, during that action the strapping becomes tighter. The effect of the strapping will be to rest the painful extensor muscles, as owing to the constriction round them they will be unable to act to their fullest extent. The action of gripping will be accompanied by much less pain, even though the patient grips his hardest, and he will acordingly tackle his game or his work with much more confidence. The benefit of strapping can be gauged beforehand by grasping the relaxed forearm between the two hands. If the patient is then able to dorsiflex the wrist and make a fist without so much pain, the surgeon may safely proceed with the strapping.

The majority of cases will clear up with these measures; hence I put them in the foreground, and reserve other remedies until these have been tried. Bone-setters get the plums; they get the patients when the probability of success is greatest. When they fail it is probably because some other condition has been superimposed on the original bony lesion and the problem of putting the patient right is passed on to us. On that account I always anticipate that a case will be troublesome when I learn that it has previously been seen by a bone-setter.

Having failed to effect a cure by manipulation and strapping we may fall back on electro-therapeutic measures, but had these been used previously—e.g., ultra-violet therapy—the skin might have been too irritated to stand strapping. There is no guide to say whether ionisation, diathermy, or light treatment will be more efficacious, and our ingenuity may be taxed to its utmost limit. Any of them may suit one case and not another, and all of them may be tried without effect. In that case galvanic acupuncture may be tried, but I keep this as a last resort, as it is the least pleasant.

Different methods of application of electricity are already well known and need not be dwelt on, but galvanic acupuncture is not so commonly employed. An indifferent electrode is fixed to any part of the patient's body and a small active electrode stroked over the painful areas. A minimal faradic current is used, and search is made in one direction for any painful part—i.e., a part which is much more sensitive to that small current than the surrounding tissues. This is marked with indelible pencil; then the electrode is moved in a direction at right angles to the former until the painful spot is again reached. This is also marked and the point of intersection is chosen for the acupuncture. A galvanic current is substituted for the faradic and a needle attached to the negative pole is inserted straight into the tissues. The current is very gradually turned on until one or perhaps two milliamperes are registering, and the needle is gently moved about to make certain that it is still at the most painful spot. This current is maintained for about six minutes, after which the pain will usually be decreased. If two milliamperes can be borne then possibly three minutes will suffice, but if the patient can only stand one milliampere, six minutes may be necessary. Two or three such places may be treated at one sitting.

Massage has its uses but it is less effective than the other measures. At one time I tried to rely solely on it, but now I seldom employ it. The only massage of any use is deep kneading into the painful tissues. Sometimes exercising the extensors against resistance is beneficial, but this can also be done *electrically*, using the faradic current.

The Manipulation.

I find it more convenient to have the patient on his back with the arm just off the table. His hand, midway between pronation and supination, is held between the operator's legs. The elbow rests in the operator's hands and is passively flexed and extended several times. Then, when the muscles are relaxed, the elbow is sharply forced a little further into extension. There is seldom any need to use an anæsthetic if the patient's attention can be diverted; the manœuvre is practically painless, the whole thing being over before he realises what is happening. A certain amount of knack is necessary, and probably the most troublesome thing is to know just how much force to use. This comes with experience and is more easily learned by seeing it demonstrated. It should, however, be stated that the force is a guarded one and stops immediately the limit of extension is reached. That is to say, the operator's hands do not follow through, there being enough way on the patient's limb to carry it as far as necessary.

G. P. Mills has also described a method, but it is immaterial what particular movement is made for the replacement so long as the bones are separated. Nature is all the time trying to get things into their proper place, and if the joint surfaces are forcibly separated the chances are that they will fly back into their correct position. This statement is made with due appreciation of the fact that I may be accused of subscribing to the popular fallacy that a bone was out of place. On the contrary I am out to shatter that belief. A snap is usually heard during the manipulation, and bone-setters have fallen into the mistake of thinking that they have actually reduced a dislocation. Nor has it been difficult or without profit to them to persuade patients that they have pushed back into place a bone which was "out." Unfortunately, however, even some medical men have fallen into the same mistake. A satisfactory explanation of what happens has never been proffered. We are told that the snap is due to the breaking down of adhesions, and there the matter apparently ends, but this is not always true. In many stiff joints adhesions are broken down, but in many joints manipulated—particularly for "tennis elbow"—there is no evidence that adhesions have been broken down. There is, for example, no effusion or swelling round the joint after the manipulation, nor is there any pain or stiffness after the operation such as we might expect from the forcible rupture of adhesions. Moreover, it is questionable if the slight force employed would be sufficient to break any but the softest of adhesions, and these could not make any appreciable sound.

My own interpretation is that one of the bones—in this case the radius—becomes fixed somewhere within the normal range of movement; hence an X ray photograph would not reveal anything abnormal. The mechanism of the fixation is not easy to understand, but just as there is a dead point on the driving wheel of a locomotive, so there may be a dead point in a joint at which the opposing sets of muscles which move the joint refuse to function, and we do know that there is an optimum position of the joint for the best muscular effort. To carry the simile further, the joint manipulation simply carries the bones over the dead point, as the engine driver does when he levers the wheel over the dead point. The bone was no more out of place than the wheel. If any further proof were required that the bone was not out of joint it is only necessary to manipulate the joint on the opposite side, when an exactly similar sound will be elicited. It is, indeed, no different to what many people do when they crack their fingers and can be produced in practically every joint of the body.

LONDON FEVER HOSPITAL.—Last year there were 1351 patients under treatment, an increase of 78 upon 1928. The medical officers' report showed that 94 more fever patients were admitted than in the preceding year. The income was £32,290, and the expenditure £33,240, an increase of £3763. At the annual meeting Sir Charles Stewart, who presided, said that the immunising of the nursing staff had almost eliminated the risk of their being attacked by scarlet fever or diphtheria.

A NOTE ON VARIOLA MAJOR AND MINOR.

BY R. W. JAMESON, M.R.C.S. ENG., D.P.H.,
BARRISTER-AT-LAW.

THE last decennial International Conference on the Nomenclature of Causes of Death, held at Paris in October, 1929, prescribed the main heading Variola, with subheadings—

(a) Variola major.
(b) Variola minor; alastrim.
(c) Variola unspecified.

Its report has not yet percolated through the various national channels; when it has done so, it should lead to a further consideration of the disease small-pox. This report, recognising as it does the present state of things, marks a definite advance in official terminology. It contradicts the view that alastrim is a disease other than small-pox, while it affirms the view that there are two forms of small-pox. It is outside its province to define the terms it prescribes.

Unless the prescribed terms, variola major and minor, are defined, the present confusion, a confusion due to lack of definition, of which we have had recent examples, will be increased rather than dispelled by this report. In the summer of 1929 the French, noting the widespread prevalence of small-pox in this country, and learning of the *Tuscania* small-pox deaths, enforced certain sanitary regulations against this country, which they relaxed on being informed by our authorities that our prevalent outbreak was, in fact, of a trivial character. In November, 1929, a report that alastrim was causing a number of deaths in Holland was explained later as an outbreak of severe small-pox in the Port of Rotterdam.

A Disinclination to Define.

In this country it is now generally admitted that there are two forms of small-pox, but there is still a general disinclination to define them. For example, in the *Times* of Jan. 8th, under the heading "Small-pox in London," it was remarked, "the notifications of small-pox in London are gradually increasing; there are now 418 cases under treatment. . . . the cases are mostly of a mild type." There is an ambiguity about the phrase "mostly of a mild type," which, but for the absence of any mention of deaths, would seem to mean that, while the minor form is the prevalent one, cases of the major form are also present. These examples point to the desirability of defining the terms we are shortly to be directed to employ.

At the commencement, in this country, of the present epidemic of variola minor, Dr. S. M. Copeman, in reporting on a local outbreak, drew up a table in which he contrasted: (a) small-pox; (b) the outbreak under investigation, which he termed varioloid; and (c) chicken-pox. His opinion that the outbreak was becoming more severe in type discounted his table of differences. Since that time official investigation, so far as it has been published, has only pronounced variola minor to be variola without attempting to differentiate between the major and minor forms. If it is held that the treatment of the two forms of small-pox should be in all respects identical, then the need for differentiation is not immediately apparent, but, as a matter of fact, large sections of the public refuse for variola minor, treatment they would willingly accept for variola major. While refusal in the first case may or may not be regrettable, it might well be disastrous in the second; but if authority declines to distinguish between the two forms, can the public be blamed for considering all small-pox trivial until experience of the major form leads them to change that view?

Differentiation in Retrospect.

In retrospect epidemics of variola major and minor differ widely; the stumbling-block in the way of differentiation of an epidemic in being is the fact that one cannot say of an isolated mild case to which form it belongs. Diagnosis of an epidemic must, then, be made by considering a series of cases; if a dozen are enough for this purpose, that is all that is required internationally. For internationally a port is not considered infected until there are groups of cases, and so international notification can be deferred until variola major or minor can be notified from a series of cases, but we should use the term variola unspecified while we are in doubt, during which period the treatment would be that for the major form. Five years ago I advocated in your columns the subdivision of small-pox, using the three terms now approved internationally, and I suggested how they might be defined, setting out the method of definition in greater detail at the Conference of the Royal Sanitary Institute at Hastings in 1927. I hold that if a consecutive series of variola major cases be contrasted with a consecutive series of variola minor cases, they will exhibit certain differences from each other. Half a dozen cases should be enough to demonstrate them, but a dozen would be on the safe side. The cases must be consecutive, not selected, for mild cases are always to be found in major outbreaks and cases of borderland severity in minor epidemics.

Briefly, the difference between the two forms being that of virulence, this shows itself in the relative severity of the worst cases and in the relative duration of the effectiveness of vaccination in the two forms. For example, the first Willesden outbreak of small-pox was of ten cases; there were three deaths from hæmorrhagic small-pox, and a child of 12 vaccinated in infancy (four marks) had a copious rash. Any one of these four cases stamps that outbreak as variola major; the child, because her vaccinal condition precluded her from being a case of variola minor, which, if she could have contracted at all, would have had but the sparsest rash by reason of her partial vaccinal immunity. I consider the records of past and present epidemics should provide plenty of similar material, and that an investigation is called for on the lines suggested above. It would, I think, be well to limit the general practitioner to the diagnosis (c) variola unspecified, and to leave the public health authority to assign the cases to the major or minor group, when able to do so, by means of a review of a series of cases.

Definition and Vaccination Policy.

Apart from the international advantage to be gained from defining the two forms of small-pox, there are other reasons for doing so. The present state of our knowledge (or lack of knowledge) of vaccination and post-vaccinal encephalitis makes the matter urgent. The Vaccination Committee reported that a risk of post-vaccinal encephalitis was incurred by children other than infants and by adolescents if they underwent primary vaccination. In the Vaccination Order of August, 1929, occurs the following:—

> "The Minister is of opinion that in the present state of our knowledge, and so long as the small-pox prevalent in this country retains its present mild character, it is not generally expedient to press for the vaccination of persons of these ages who have not previously been vaccinated, unless they have been in personal contact with a case of small-pox or directly exposed to small-pox infection."

It seems obvious that, whatever is advised, primary vaccination at the dangerous age is being practised less and less, and rightly so in our present state of uncertainty. We are supplied with one Government lymph only, for use at all ages under all conditions, we are told to use it for infants and to repeat the dose at seven and again at 14 years of age; therefore, presumably, it confers immunity for seven years, but if so, surely it is unnecessarily potent for the vaccination of contacts at the dangerous age, where all that should be attempted is to confer an evanescent protection by means of a minimal dose of an agent which may be for them of a lethal character. From time to time one hears of vaccination enthusiasts who say, quite rightly, that a small-pox mortality would restore the prestige of vaccination. I hold that against variola major its use is imperative, but that it is not justifiable against the minor form because of the trivial nature of that form of small-pox and the seemingly dangerous nature of the prophylactic; and that the failure to distinguish between the two forms is bringing vaccination into discredit.

An Analysis of Small-pox Deaths.

In his last annual report the Chief Medical Officer of the Ministry of Health supplies another argument in favour of subdivision and definition, for he quotes the Registrar-General's figure of 53 small-pox deaths in 1928, and then follows it by a Table giving particulars of these deaths. The list begins with a person aged 89 and ends with one aged 84 whose death certificate reads: (1) (*a*) heart failure; (*b*) old age; (2) suspected variola (petechial); no p.m. Of these 53 so-called small-pox deaths, 23 are over 70 years of age, 4 of them are infants; of the remaining 26 it may be said that 15 of them have other diseases mentioned on their certificates, which make it probable that the small-pox was, if of any, then of only secondary importance as a cause of death, and we are left with only nine out of the Registrar-General's total of 53 who may have died of small-pox. Indeed, it seems not unreasonable to assume that variola minor is a non-fatal form of small-pox save at the extremes of age or in the presence of some disease or injury which is itself a common cause of death. Quite two-thirds of the variola minor cases occur in the age-period 1–30 years, while the Registrar-General records only five small-pox deaths for this age-period; it would be interesting to learn whether or no any of these deaths were due to the severity of the small-pox, for this is the age-period when vaccination may be dangerous but is deemed necessary for contacts. The vaccinator who vaccinates persons of this age in the light of the Vaccination Committee's report incurs a grave responsibility even though supported by the dictum of a Minister. The apparent eccentricities of the Registrar-General are usually explainable as due to international regulation; the method of estimating small-pox deaths is roughly to count all persons with small-pox who die as deaths from small-pox; this may have been fairly accurate when the prevalent disease was variola major, the C.M.O. has shown how very incorrect it is when the prevalent disease is variola minor. One hopes that, when the new report appears, the Registrar-General will receive fresh international guidance; if he does not, then it will be necessary for him to issue both an international and an amended report of small-pox deaths, of which Sir George Newman's Table would seem to be a forerunner.

For the last ten years variola minor has steadily increased in this country, therefore as regards this form of small-pox the plan of treating variola as an indivisible unit has largely failed. There have been several small outbreaks of variola major where our methods would appear to have been successful, notably the *Tuscania* outbreak in which the public press emphasised the subdivision. Administrative methods, even if considered ideal, require to be adjusted to actual conditions. The primary condition for effectiveness is that the method be acceptable, and this is far from being the case at present. It is of interest that in 1923 Gloucester, a town rabidly antivaccinist, allowed variola minor, under the pseudonym of chicken-pox, to proceed unchecked for six months, the cases were then isolated in hospital as small-pox; a few cases continued to occur, but by the end of the year the epidemic was at an end. Elsewhere cases are isolated in hospital, contacts are pursued with vaccination, and in some places the epidemic lasts for years. Active measures at the start of an epidemic may, and sometimes do, appear to bring an epidemic to an end, although it might have died away without them, for we know that a large proportion of the unvaccinated contacts escape the disease, and that many cases, because of their mild ness, escape detection. Variola minor having established itself in an area it seems futile to attempt to eradicate it.

Conclusion.

On the whole, then, the differentiation and definition of variola major and minor based on the review of a small series of cases does not seem to be difficult. The existence of two forms is generally admitted; internationally their existence is to be officially recognised; the public here already subdivide smallpox. Any medical measure to be effective must be acceptable. Our treatment of variola minor has been a failure because unacceptable. Unless the two forms of variola be defined the same treatment is necessarily advocated for each. In view of the uncertainty in regard to vaccination and post-vaccinal encephalitis variola minor should be defined so that our advocacy of vaccination in regard to it may be reconsidered. In fact the Registrar-General's return gives an erroneous impression of the severity of variola minor. Variola major, if separated from the minor form, will be more easily treated. Non-epidemic vaccination is not acceptable to a large section of the community, therefore the ideal of the general immunisation of the community is at present impossible of realisation, and the epidemic treatment of variola major should occupy our attention, but until the major and minor forms are defined and separated we remain in a state of ignorance potentially dangerous.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ORTHOPÆDICS.

AT a meeting of this Section on March 4th Mr. D. **McCRAE AITKEN**, the President, took the chair, and Mr. S. A. S. **MALKIN** opened a discussion on

SPASMODIC FLAT-FOOT.

The scarcity of references in the literature, he said, made definition difficult, but he suggested that spasmodic flat-foot be defined as a condition in which the foot, without evidence of a bony lesion, was held in a valgus position by spasm of the peronei. Sir Robert Jones, in his "Notes on Military Orthopædics," had described the condition vividly. The patient limped with a springless gait, with the feet practically rigid and the toes pointing out. The feet were both everted and the inner border over the region of the scaphoid appeared thickened and even angular. There might be a history of injury such as a fall on the feet; usually, however, the patient could not account for the trouble. The pain was often acute and the feet perspired abnormally. Removal of the boots gave relief. The patient could not invert the foot and, if he tried to, the peronei became rigid. Pain was felt on pressure over the deltoid ligament, the scaphoid, and the tip of the external malleolus where it impinged upon the os calcis, and tenderness over the peronei along the outer border of the foot. Gentle attempts to invert the ankle produced much pain, the peronei standing on guard to resist the movement. If, however, the patient's attention were distracted and the foot, after gentle pressure in this direction, were suddenly and forcibly inverted and held, its character and contour were completely changed. It was no longer rigid, osseous changes were obviously absent, and the general appearance was almost normal. When the foot was released, the rigidity and deformity returned.

The question arose which was primary: the spasm of the peronei or the valgus position; and of whether the spasm was merely protection or required some other explanation. Mr. Malkin outlined the anatomy of the foot, and the mechanism by which flat-foot was produced. Tests made by the speaker with a spring balance on groups of children had shown that the inverters were stronger than the everters in normal subjects, and in cases of flat-foot after treatment, but that in patients undergoing treatment the everters were stronger. If, therefore, in these patients there was a lesion of the subastragaloid and mid-tarsal joints, protective spasm might be expected to hold the foot not in inversion but in eversion. This position—normally a position of rest—led to continuous and intensive strain on the ligaments and joints involved, and might lead to adaptive shortening of the muscles. The result was a vicious circle. An exaggerated position, no longer one of rest, was adopted, and there was a loss of postural tone and partial reversion to a position comparable with that of the anthropoid. The weakened everters were placed under the disadvantage of having to restore the arch in order to invert and adduct the foot. Protective spasm would only be evoked by some injury of the joints, and spasmodic flat-foot was more likely to be a protective spasm if (1) there had been an actual or potential injury or strain of the mid-tarsal and subastragaloid joints, and (2) the spasm affected other muscles besides the peronei. Statistics showed that a large proportion of cases gave a definite history of injury or were of an age when liability to trauma or strain was greatly increased, and it was generally accepted that most patients showed spasm of the extensor longus digitorum as well as of the peronei. These facts, combined with other evidence, suggested that the spasm was protective, and there was no reason to doubt that it was at any rate secondary.

Treatment.

Treatment had varied according to whether the condition was regarded as primary or secondary. Some authorities thought that spasm of the peronei was a self-limiting disease and needed no treatment; Naughton Dunn, taking a different view, had crushed the peroneal nerve, and others had anæsthetised it or had infiltrated the peronei and extensors. Good results had been reported. Others again had wrenched the foot into an inverted position, dividing or exsecting part of the peroneal tendons and then treating for flat-foot. Adequate training in childhood could prevent many cases, for the deformity could usually be voluntarily corrected by patients under fourteen and was not then true spasmodic flat-foot. The treatment in this group consisted of flat-foot exercises, particularly for the inverters; general postural re-education; inside wedges and night splints to hold the feet inverted. The results were uniformly satisfactory. In cases where the spasm disappeared under anæsthesia the treatment was manipulation, fixation in full inversion and adduction for six weeks, and then exercises. Outside irons and inside T-straps were fitted if the inverters were particularly weak. In cases where there was definite contracture, this treatment was preceded by division of the peronei. The results had been completely satisfactory in 8 cases out of 15, and 5 had been improved. The rarity of the condition in the speaker's experience might, he thought, be due to better postural instruction in schools.

Mr. E. P. **BROCKMAN** analysed 27 cases, most of whom had attended at 15 or 16 years of age, having been at work a year or two at occupations necessitating much standing about. The left foot was the more often and more severely affected. Quite a number had given a history of accident, but this had usually been trivial, indefinite, and difficult to associate with the symptoms. All the patients had had good general health. Spasmodic pes planus was a clinical entity and quite distinct from other varieties of flat-foot; it was the commonest type in adolescents. The fore-foot was held in rigid abduction, eversion, and dorsiflexion by the two peronei and the extensor longus digitorum. Pain arose both from spasm of the muscles and from the resulting arthritis of the tarsal joints. Pressure over the outer side of the foot, especially over the calcaneo-cuboid joint, was painful, and showed inflammation of this joint or its capsule. There was no tenderness over the inner side of the foot. He agreed that the spasm must be protective, and suggested that its object was to limit the movement of the calcaneo-cuboid and cubo-metatarsal joints. The resistance of the condition to treatment suggested some cause other than a purely mechanical one; he suggested a primary mechanical arthritis with a superadded infection or intoxication, and mentioned the theory of tonsillar infection.

Treatment had restored the foot to its normal shape in 5 patients only out of 18 he had examined; the remainder had been freed from symptoms but their feet had remained rigid, with some permanent contraction of the peronei and extensor longus digitorum. The measures adopted had been manipulation under anæsthesia, plaster fixation in abduction and inversion for six weeks, exercises, and wedged shoes. Tenotomy of the peronei and excision of a portion of the muscles had not appeared to produce permanent improvement. Outside irons with T-straps had relieved the symptoms in a few patients who had continued at work. In early cases the feet could be manipulated comfortably into good position under anæsthesia, but in late cases correction was impossible. Mr. Brockman deprecated the removal of these patients from work for a treatment which would probably be useless, and recommended that they should simply be provided with supporting devices.

Mr. NAUGHTON DUNN said that the increase in facilities for preventive treatment had greatly reduced the incidence in the last 20 years. If peroneal spasm was present the child could not stand on the outer border of its feet; this test distinguished the condition from ordinary flat-foot. In questions of legal compensation he always held that an accident must have been a predisposing cause. Early cases should be put in plaster in the correct weight-bearing position, and treated by rest followed by exercises. The correct position was the most important part of the treatment of all cases. When manipulation had restored the arches, the foot should be inverted at the subastragaloid joint and the os calcis forced in and fixed under the astragalus in its proper relation to the bones of the leg. The fore part of the foot should then be pronated so that the first and fifth metatarsal heads were weight-bearing surfaces. There was then no need for the position to alter when the foot was taken out of plaster. Where, although the condition was three to six months old, the arches could be easily restored under an anæsthetic he advised the operation of cutting down over the head of the fibula, exposing the three branches of the external popliteal nerve and crushing the musculo-cutaneous nerve. This threw the peronei longus and brevis out of spasm. After nine days the patient could start walking and simple flat-foot exercises. These muscles remained out of spasm for three or four months, after which time the patient had regained normal balanced control of the tarsal joints. The operation was useless when osseous flat-foot had set in or true shortening of the peronei had occurred. In old-standing painless cases with tarsal arthritis it was probably better not to interfere, but in recent osseous flat-foot the peronei should be divided, the deformity corrected, and the feet fixed in plaster in the correct position

“Tonsillar Foot.”

Mr. W. H. TRETHOWAN said that the condition had nothing to do with flat-foot, but was so constantly associated with large and septic tonsils that he had named it “tonsillar foot.” The primary incidence of the infection was in the astragaloid and subastragaloid and not the calcaneo-cuboid joint. The name “flat-foot” was bad; most patients in the early stages had very good arches. They were cases of spasmodic valgus. The condition most resembling it was the foot of rheumatoid arthritis when the mid-tarsal and subastragaloid joints were involved first. A minor injury might predispose. Treatment was prolonged rest, re-education, and the removal of septic foci. He had long given up manipulation and plaster. Only the earliest cases recovered. It was intractable because adaptive and osteophytic changes arose very early. The pain was on the outer side of the joint, about the region of the short extensors of the toes; it was, he thought, secondary, and due to pinching of the synovial membrane or capsule through spasm.

Mr. E. MUIRHEAD LITTLE recalled that 50 years ago the condition had been much more common and had chiefly occurred in young adults such as errand-boys, in beer-drinkers, and in elderly waiters. When the spasm had given way under anæsthetic, fixation in approximately the equinovarus position, with surgical measures if required, had given good results, but it had been considered important that the patient should abandon the occupation which had caused the trouble. He considered that Mr. Trethowan's remarks should be followed up.

Mr. P. B. ROTH recommended manipulation, division of the peronei tendons and, generally, of the extensor communis digitorum; fixation in plaster for a month, and then wedged and T-strapped shoes. The condition usually occurred in “curious-looking” boys and girls, not normal ones. The definition should include the expression “painful,” and admit spasm of other muscles besides the peronei.

The CHAIRMAN, considering the evidence for a primary spasmodic flat-foot, recollected cases in heavy, flabby messenger boys, not ordinary hardy adolescents, but in what a colleague had called the “mucous” type. He had wondered at one time whether the condition was not associated with a thymus disorder. He had seen the spasm disappear in sleep, but not always in cases diagnosed as spasmodic flat-foot. Sir Robert Jones, before the days of plaster, had corrected the valgus of the heel by putting the foot up for three weeks in full abduction, with a large pad of wool between the heel and the sub-splint, and the sole turned right in; he had then fitted ordinary crooked shoes. Mr. Aitken himself had reverted to this method in preference to plaster. Walking on the outside of the foot was incorrect; when patients walked in plaster the fore part of the foot must be in a normal position.

Mr. LITTLE remarked that hot-air baths relieved the spasm.

Mr. MALKIN replied.

SECTION OF COMPARATIVE MEDICINE.

A MEETING of this Section on Feb. 26th, with Capt. S. R. DOUGLAS, F.R.S., the President, in the chair, was devoted to

CANINE DISTEMPER.

Mr. THOMAS DALLING said it was now known that there was a specific virus associated with canine distemper, that it set up a special train of symptoms when inoculated into or brought into contact with suitable dogs, and that by means of suitable antigens a natural immunity could be induced against infection. In the experience of Mr. Dunkin and himself, and in the records of cases sent by others who had used the antigen which he and Mr. Dunkin had prepared, it had been successful in 99 per cent. They had been asked to undertake the making and issuing of a prophylactic preparation on a large scale to members of the veterinary and medical professions. On the whole, the results from the use of this prophylactic had been fairly good. There had been failures, but some veterinary surgeons had had nothing but excellent results. In two series of 140 and 217 cases there had been no failures. The untoward happenings could be divided into three groups: (1) illness following immediately after injection of the vaccine, or the virus, or both; (2) nervous disturbances following its use, coming on perhaps months later; (3) a breakdown of immunity a considerable time after the injection. As to the first of these, if on receiving the vaccine the dogs were healthy and had not recently been exposed to the infection, they showed no appreciable departure from normal health. When the virus was injected seven days or more after the vaccine, a proportion of dogs showed some disturbance of general health, in the form of raised temperature, watering of the eyes and nose, and some diarrhœa. It was usual for these symptoms to be transient; but some of the animals seemed to be severely affected and required careful nursing. In a few death occurred, but the fatality risk was under 1 per cent. In the second category came fits of all degrees; some said that hysteria resulted from the vaccine and virus. In rare cases choreic symptoms were noted, and there was a record of one case of true encephalitis, the disease being confirmed at autopsy. When fits occurred months afterwards they were attributed to a breakdown in immunity.

There were several possible explanations for the mishaps. One was that the quality of the vaccine and virus might have been defective. Testing by the Laidlaw and Dunkin method, only a vaccine which fulfilled the requirements was issued. It was necessary to know the exact time for obtaining tissues, so that they should contain the maximal quantity of virus; it was also important to ensure that the living virus in the tubes should arrive for use in a potent condition. One dose of vaccine should be followed by the use of the living virus in order to obtain the greatest immunity. One cause of mishap, clearly, was the inoculation of dogs which at the time were exposed to infection. Temperatures should always be taken before subjecting the animals to the injection. Pups younger than three to four months should not have the treatment, though there were records of dogs having the treatment after six weeks old. Some post-mortem examinations showed that the distemper virus existed in the tissues of some dogs which had been immunised, but the immunity induced did not suffice to protect against natural infection. In some cases of apparent breakdown the presence of the distemper virus could not be demonstrated; some had the pneumococcus and the symptoms of pneumonia, and a hæmolytic streptococcus was isolated from the lungs. In some cases the culprit was *Bacillus bronchisepticus*.

Secondary Organisms.

Mr. G. W. **DUNKIN** thought it was desirable that the question of distemper immunity should be discussed, because of the publicity which had been given to it. The position was still the same as a year ago—namely, that it was possible to confer a lasting immunity on dogs and ferrets by means of suitable agents. Experiments, many of them voluntary, carried out under ideal conditions, dealt with 2000 dogs and hounds, which were treated by 90 veterinary surgeons, and the deaths from all causes following inoculation amounted to less than 1 per cent. of the animals treated. Since then many thousands of doses had been distributed. In all the experimental work with which the speaker was concerned there was only one case of pneumonia. The latter, however, was common in field cases, and a frequent accompaniment of the pneumococcus was a streptococcus. It had yet to be settled whether dogs which had been immunised against distemper by the vaccine-virus method were also protected against those bacterial infections which were met with in the field. The diagnosis of distemper cases in the field was not easy; 99 per cent. of the hounds examined had shown the presence of the pneumococcus, so there was at least a double infection. Mr. Dunkin was now quite satisfied that a dog which had been protected by a vaccine of good quality, followed by a living virus, was protected not only against distemper but against the usual secondary infections encountered in such cases. The diagnosis of distemper from *B. bronchisepticus* and streptococcus infection was not likely to draw dogmatic statements from even the most experienced veterinarian; the aid of the laboratory must be enlisted. It was very important that the dogs should be in good health before receiving the injections. The virus of distemper was very unstable. He did not consider that a lasting immunity could be conferred by the injection of the vaccine without using also the living virus. A vaccine, properly prepared, could not cause illness; it consisted of a 20 per cent. suspension of finely minced dog tissue which originally contained the living distemper virus, but which had been killed by formalin. A small quantity of ammonia was added to prevent irritative effects. Therefore if a dog was ill before the virus was given, there was only one explanation—namely, that it was in the incubative period of the disease before the virus was given. If the illness was due to some other infection, naturally the virus could not be held responsible.

Discussion.

Mr. **HUMPHRY NEAME** hoped that the public would gain a right conception on the matter as a result of this meeting. One of the symptoms which the dog with distemper showed was a parenchymatous keratitis, quite distinct from that condition of the conjunctiva which caused it to discharge. A dog which had this keratitis did not show a clear-cut image of a window or other object on the cornea; the image was hazy and woolly. If that could be regarded as diagnostic of distemper, it was a sign readily recognised and therefore of value.

Dr. M. J. **ROWLANDS** also urged that the public should be informed as to the true state of knowledge on the subject; the misleading statements in some newspapers led to wrong policy in a number of kennels.

Mr. S. G. **BILLINGTON** said that for nearly seven years he had been investigating canine distemper as an example of a specific infective disease. He had made a study of the habits of the causal organism, had tried to evolve a curative remedy, and to form conclusions as to prophylaxis. In 1923 he took 40 blood cultures from dogs in various stages of distemper, and obtained the same organism in 36 of them. This organism he then referred to as the distemper leptothrix, and he considered that in its virulent stage it was a filter-passer. There were three definite stages of the disease. The first was the early, pre-secondary infection stage; the second the pre-moribund stage—i.e., that in which the infection was distemper plus some secondary invading organism. In the third or moribund stage the animal had absorbed a lethal dose. Stage 2 was the important practical one. A syndicate had been formed to distribute his remedy, but he had been unable to get a sufficient clinical backing. He decided to make a fresh start, on virgin soil—namely, America. The University of Pennsylvania were now testing it, and the reports so far were that it was very successful. Prophylaxis was very difficult, for the weakness in the susceptible animal was probably due to endocrine inadequacy.

Mr. **LIVESEY** had arrived at the conclusion that from the point of view of the clinician it was difficult to say when a dog was free from distemper. It had been pointed out how important it was that before making the injection the dog should be healthy, the thermometer reading being relied on for this. In the incubative stage the temperature might rise early, but fall a little later, and the reading might be taken at this fall and a wrong conclusion arrived at. Three weeks' isolation before carrying out the injections was his recommendation. He hoped the diagnosis of distemper would be very definitely arrived at, because at the moment three diseases were receiving that name, apart from complications. He did not know whether chorea in the dog was a sequel of the pure distemper infection.

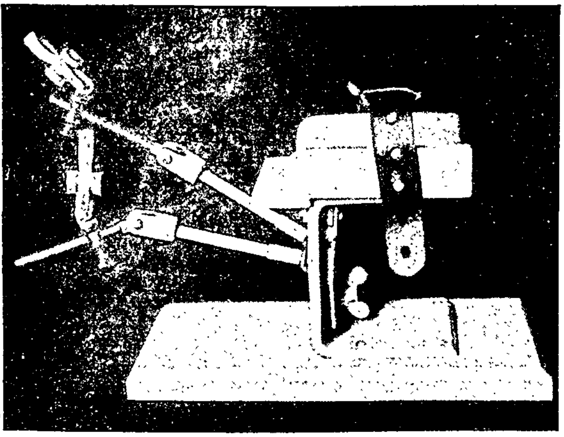
Mr. A. A. **COMERFORD** agreed with another speaker that it was difficult to know what hounds were suffering from distemper. He related some experiences in a number of kennels which seemed to show that the virus supplied for the purpose was not potent when actually injected. He knew of foxhounds which were immunised with material received from Mill Hill three years ago, and those dogs were still standing up against distemper, and therefore he assumed that they were immune for life.

Mr. W. TURNER WARWICK writes:—May I amend the report (THE LANCET, March 1st, p. 457) of the remarks I made in the discussion at the Royal Society of Medicine by the Proctological Subsection on Factors Making for Safety in the Surgery of Colon and Rectum? Actually I described and advocated the two-stage abdomino-perineal operation by the method of Coffey for high rectal and pelvi-rectal growths, and made the following remarks: "The operation thus performed is within the powers of an average surgeon (in contra-distinction to the ordinary one-stage abdomino-perineal operation); the after-treatment demands no special experience on the nursing side, and the late results should in no way differ from those of an abdomino-perineal operation successfully performed in one stage."

New Inventions.

A NEW DEVICE FOR OPERATIONS ON THE HAND.

THE small instrument here illustrated was designed by Mr. J. H. G. Robertson (60, Pentland-terrace, Edinburgh) to overcome the difficulty of maintaining suitable exposure and immobility while operating upon injuries of the hand. The wrist is held in a shallow gutter by an elastic strap, the shelf projecting as far as the middle of the metacarpal region. The construction of the two arms is made clear in the diagram; both work on a ball-and-socket joint and have a free range of movement. By means of the butterfly nut and hinge a suitable degree of stiffness is maintained and complete immobility can be secured when required. The joint in the middle of the arms is moderately stiff and needs no adjustment. The clips are fitted with springs enabling them to retain a firm hold of the fingers. Both clips hinge freely on their sliders in the axis of the rods, and the sliders themselves can be moved up or down the rods and fixed by a turn of the screw. With the palm either upwards or downwards by grasping a finger in each clip and manipulating the arms any required position can be maintained. The complete extension and wide abduction obtainable are of help in such an operation as amputation, particularly where no assistant is available.



Reviews and Notices of Books.

A SYSTEM OF BACTERIOLOGY IN RELATION TO MEDICINE.

Vol. II. By C. H. BROWNING, W. BULLOCH, J. H. DIBLE, A. FLEMING, F. GRIFFITH, R. TANNER HEWLETT, J. E. MCCARTNEY, T. J. MACKIE, D. G. S. MCLACHLAN, J. W. MCLEOD, W. MAIR, E. G. D. MURRAY, G. H. PERCIVAL, W. M. SCOTT, A. L. TAYLOR, W. J. TULLOCH, H. D. WRIGHT. Medical Research Council. London: H.M. Stationery Office. Pp. 420. 21s.

THE second volume (the third to appear) of this important work consists of seven chapters, each containing a full account of a group of bacteria and their relations to disease. It is a relief to find that the well-known titles of Pneumococcus, Meningococcus, Gonococcus, and *B. influenzæ* are used and that the less familiar "generic" and "specific" titles of *Streptococcus pneumoniæ, Neisseria gonorrhϾ, N. intracellularis*, and *Hæmophilus influenzae* are not present currently in the text. The classification of bacteria as far as is possible into genera and species is a useful systematic exercise, and may lead to important conclusions regarding their evolution or pathological action, but, as in many other groups of living things, generic names are apt to be changed as knowledge advances, and therefore either an accepted title, or the specific name where this has some fixity, is often the best for practical usage.

Seventeen authors have contributed to this volume, which includes interesting and valuable historical notes by Prof. Bulloch. The chapters on gonococcus by Prof. Tulloch, meningococcus by Dr. Murray, and staphylococcus by Dr. Fleming are, in one sense, the most complete, since knowledge of their subject matter has grown relatively little of late years. This is especially true of the staphylococcus, which has been studied longest. Strains of meningococcus from epidemic sources form, as is natural, the chief basis for Dr. Murray's chapter; he presents a wealth of important facts, including many personal observations. A fuller study of strains from sporadic cases would, perhaps, give a wider horizon to the subject. Prof. Tulloch's account of the gonococcus covers a larger field, corresponding to the more continuous and varied clinical sources of cultures. In spite of his assertion that absorption of agglutinins will readily distinguish the gonococcus from the meningococcus it is not clear that this would always be possible, more particularly in the case of strains from septicæmia or joint lesions associated with the less known types of organism. This doubt is emphasised by his statement that the gonococcus may cause meningitis, and the meningococcus vulvitis. To the chapter on pneumococcus Dr. Mair contributes 13 pages on cultural characters and biochemical activities, including a full account of autolysis and bile solubility. Prof. McLeod summarises the very extensive work on pathogeny in pneumococcal infections, and Dr. Griffith deals with the significance of "types" and their various antigens, serum therapy, and prophylactic vaccination. Prof. Browning writes on the action of antiseptics in vitro and in vivo. Much of this chapter refers to work so recent and suggestive of wider application that it especially deserves careful study. Intensive investigation of the streptococci has been pursued by many workers, especially since the war, and the difficulties of identification, variation, and classification in the whole group are critically surveyed. In an article of 150 pages Prof. McLeod devotes 42 pages to the general bacteriological aspects, including the hæmolytic and other biochemical properties, and Dr. Mackie, Dr. McLachlan, and Dr. Percival discuss the hæmolytic streptococci in human disease in 29 pages. Much of the newest work on this sub-group centres round streptococcal toxin and the relations between strains from erysipelas, scarlet fever, and puerperal fever. The stricter definition of hæmolytic power to the ability to form a heat-labile soluble hæmolysin, as insisted on by Prof. McLeod, might lead to a clearer conception of the relations of the pathogenic group. The section of 26 pages by Dr. Wright on the heterogeneous group of "mouth streptococci" includes the various strains known as *S. viridans*, and many of the strains which are less acutely pathogenic for man and animals. Prof. Dible describes in 13 pages the varied characters of "bowel streptococci," and among them recognises a group of "enterococci" with definite characters but low or doubtful pathogenicity. Anaerobic streptococci, dealt with by Dr. Taylor, are held sometimes to increase the morbid changes when associated with other bacteria.

What is known of the action of chemical substances on streptococci is told by Prof. Browning. The excellent chapter on the "Influenza Group of Bacteria" is written by Dr. W. M. Scott, with the exception of a section by Dr. McCartney on *B. pneumosintes*. Besides a description of the bacillus of Pfeiffer, its cultural needs, and the serological, morphological, and biochemical differences between the strains, there is a thorough and well-balanced discussion on the causation of influenza and the part played by the various secondary invaders. The possibility that a virus is the essential ætiological factor is fully considered, but the evidence in its support is held to be unsatisfactory. The apparent identity of the Koch-Weeks bacillus with *B. influenzæ* is commented on. The ability of Bordet's bacillus (*B. pertussis*) to grow without the accessory substances in the media required by *B. influenzæ* is accepted by Prof. Hewlett as a reason for placing it in a separate group. Bordet's bacillus is regarded as the cause of whooping-cough, and the diagnosis of the disease by means of cultures and its treatment by vaccines is discussed. In the same chapter are also included Ducrey's bacillus of chancroid and the Morax-Axenfeld bacillus of conjunctivitis.

If the remainder of the "System" is up to the standard of the volumes so far published, the Medical Research Council may be well content with their undertaking.

PERNICIOUS ANÆMIA.

By L. S. P. DAVIDSON, M.D., F.R.C.P.E., Lecturer in Systematic and Clinical Medicine to the University of Edinburgh; *and* G. L. GULLAND, M.D., F.R.C.P.E., Professor Emeritus of Medicine in the University of Edinburgh. London: Henry Kimpton. 1930. Pp. 293. 25*s.*

IN spite of the interest which it has attracted for the past half century, and the close attention which has been focused upon it in a concentrated degree for the past two or three years, our knowledge of pernicious anæmia remains disappointingly small. The dictum of Cohnheim that abnormal formation of the blood is the fundamental factor in the disease has become firmly established, and that is something. As to what brings about that abnormal formation we remain in darkness—a darkness in which the searcher is continually knocking up against the debris of shattered theories mainly with a bacteriological foundation. Dr. Davidson and Prof. Gulland make a thorough and more or less dispassionate survey of the geography of this limbo, the net result of which is negative; in spite of ethereal sulphates, portal hæmolysis, focal sepsis, auto-intoxication, intestine, sepsis, and many another promising theory, the way to an understanding of pernicious anæmia remains hidden. It is true that W. B. Castle's recent work on the relationship of the stomach to the condition does offer some hope of a better understanding, but the time is not yet ripe for its evaluation. On the ætiology of the disease, then, the authors find themselves unable to come to any definite conclusions. Faced with the facts of changes in the nervous system, bone-marrow, and stomach, they postulate a congenital defect in all these tissues and in the liver as well. They appear to place pernicious anæmia in the class of the abiotrophies. That, however, is not the whole of the story. They believe that even in the face of the abiotrophic constitution some precipitating factor is necessary. As to what this may be, they do not venture beyond the guarded statements that "the intestinal tract is of prime importance," and that "the liver with its contained 'blood hormone' is the connecting link between the bone-marrow and the intestinal tract."

Twenty-five pages of the book are devoted to a full reproduction of the original paper in which Dr. Davidson reported his demonstration of the fact that the fæces of pernicious anæmia patients contain more organisms than those of normal controls; a further 12 are devoted to the Milner Fothergill essay for 1928; the concluding 30 pages comprise an admirable appendix by Miss Ruth Pybus, sister dietetian to the Edinburgh Royal Infirmary, on the dietetic treatment of pernicious anæmia; this section contains many useful recipes and suggestions for the cooking of liver, and should prove of the utmost value.

THE NEUROSES.

By ISRAEL S. WECHSLER, M.D., Associate Professor of Neurology, Columbia University. London W. B. Saunders Co., Ltd. 1929. Pp. 330. 18*s.*

WE are in substantial agreement with the opening sentence of Dr. Wechsler's preface, that "the neuroses constitute the most ill-defined and least understood entities in the whole domain of medicine." And we believe, too, that the constant war between the rival camps of the somatists and the psychopathologists (of which he speaks) will continue just so long as there is indefiniteness as to the nature and pathogenesis of neurosis. Introductory chapters deal with the historical aspect of the subject and supply a detailed account of mental mechanisms and of the way in which these are utilised to support various current hypotheses associated with the names of Adler, Jung, Freud, and others. Dr. Wechsler avows himself in the main a follower of Freud, and his book accepts a view of neurosis ætiology in accordance with the contentions of that psychiatrist. The classification adopted by the author includes: (1) "actual neuroses" (anxiety neurosis, neurasthenia, hypochondria); (2) "psychoneuroses," divided into "transference neuroses" (hysteria and compulsion neurosis), "narcissistic neuroses" (paraphrenia, schizophrenia, manic-depression, and paranoia), and other "regression neuroses" (perversions, &c). The rest of the volume is taken up with their systematic description and treatment. So far it follows accepted Freudian lines more or less, and is well written and well arranged. But though Dr. Wechsler begins by noting the ill-defined character of his subject we can find nowhere in the book any attempt to define it. We miss any exact account of what neurosis is actually taken to signify. The author considers occupation neurosis a "hysterical conversion phenomenon," and we must suppose he thinks the same of the "cramps" of watchmakers, milkers, blacksmiths, tailors, flute-players, and so forth, since they are mentioned in the same section. Then how does he explain their monosymptomatic character? On the other hand, he entertains doubts of the "neurotic" nature of tics, torticollis, spasms, and myoclonus, seemingly because of the advent of epidemic encephalitis and recognition of dystonia musculorum deformans. He does not appear to have faced the question of similar clinical phenomena being of diverse and distinctive ætiology; torticollis, for example, looks the same outwardly whether it is a tic, a spasm, a paralytic modality, an occupation neurosis, a sequel to encephalitis, or what not. Again, impotence is taken to be a neurotic manifestation, especially of hysteria. But unless neurosis is defined the reader is no wiser. Impotence is neither more nor less than a symptom; it may be the expression of a number of entirely different factors acting on a physiological mechanism; among these, no doubt, is one that is psychical, but there are others.

The symptom itself is the same for all—viz., inability to perform the sexual act. In our view confusion results inevitably from any failure to realise that one and the same symptom can arise from disorders at different physiological levels—inclusive (if it be allowed, as it ought to be) of the psychical.

LEPROSY.

Symptoms, Diagnosis, Treatment and Prevention. Second (revised) edition. By ROBERT G. COCHRANE, M.D., Ch.B., M.R.C.P., D.T.M. & H., Secretary, British Empire Relief Association; Hon. Medical Adviser, Mission to Lepers. With a Foreword by Sir LEONARD ROGERS, M.D., F.R.C.S., F.R.S. British Empire Relief Association. 1930. Pp. 68. 2*s.*

IN a small compass this is a succinct and intelligible summary of modern knowledge about leprosy. In some eight short chapters the lesions, course, signs and symptoms, diagnosis, prognosis, prevention, and treatment are described. It is the last section to which the reader will undoubtedly turn for help, and here he will find the various methods of treatment, drugs, and dosages judiciously and helpfully set out. More than this, the author has studied his subject so diligently tha the is able to supply indications and contra-indications for each course advocated. We are glad to find in him no blind advocate of any particular line of treatment, but one who assigns to each a particular sphere of usefulness. A series of appendices giving details of staining methods and serological tests completes the volume. No worker in leprosy should be without this vade-mecum, which is a testimony in itself to the work of the British Empire Leprosy Relief Association.

BODILY CHANGES IN PAIN, HUNGER, FEAR, AND RAGE.

Second edition. By WALTER B. CANNON, M.D., S.D., LL.D., George Higginson Professor of Physiology in Harvard University. London: D. Appleton and Co. 1929. Pp. 404. 12*s.* 6*d.*

IT has often been asserted that physicians, apart from neurologists and psychiatrists, pay little attention to the effect of the emotions upon the body, either in health or in disease. It is doubtful whether this charge could ever be justly brought, but it is certain that at the present time no one in the medical profession or out of it is unaware of the influence which the mind and the emotions may exert upon bodily processes. The general public is, in fact, only too ready to believe in "miracles" achieved by faith-healing in one form or another. Prof. Cannon gives an account of the influence of the emotions upon the body, limiting his facts to those which up to the present have been experimentally ascertained. Since 1915, when the first edition of his book appeared, a large amount of work has been done, both in America and in Europe. The early chapters of the book, dealing with the effect of the emotions upon digestion, upon adrenal secretion, and upon the blood-sugar, are, apart from the inclusion of the newer work just mentioned, for the most part unchanged.

The most noteworthy additions to the second edition are two chapters dealing with the theory of the emotional mechanism. In the first of these new chapters Prof. Cannon deals with the James Lange theory; little in that theory commends itself to him, though when discussing expressed emotion in experimental animals, he admits that "we have no real basis for either affirming or denying the presence of 'felt emotion' in these reduced animals." It is, naturally, the "felt emotion" with which we are principally concerned, so that it is permissible to doubt the value of experiments on animals when this "felt emotion" is in question. The theory which is here developed to replace the James Lange theory is based on the clinical work of H. Head and others, and upon experimental work (again upon animals) in Prof. Cannon's own laboratory. According to this theory, the optic thalamus is the centre in which emotional processes are localised. Other new chapters deal with the emotional derangement of bodily function, the physiology of thirst, and with the recent work upon the part played by the spleen in emotional polycythæmia. The book concludes with an appeal for the satisfaction of the fighting instinct by some means other than war, and the suggestion is put forward that the only outlet suitable to the conditions prevailing in a civilised or semi-civilised world is to be found in international athletic contests.

HEAT PYREXIA. NO HEATSTROKE. NO HEAT FEVER.

By C. J. MCCARTIE, M.D., M.Ch., Lieut.-Colonel, I.M.S. (retired). Dublin: Browne and Nolan, Ltd. 1930. Pp. 27. 1*s.*

IT is very difficult to discover the object of this little tract, for it is little more. It is a wandering statement purporting to show that there is *no heat fever, heat stroke or sun stroke*, but as to what other to substitute for these well-hackneyed terms the author is quite unconvincing. The last fatal illness of a well-known surgeon is detailed, and no other explanation is advanced than that of a clear case of heat stroke.

L'ÉPILÉPSIE.

Conceptions actuelles sur sa pathogénie et son traitement. By Ph. PAGNIEZ, Physician to the Hôpital Saint-Antoine. Paris: Masson et Cie. 1929. Pp. 199. Fr.26.

THERE is no better expression than the French "mise-au-point" to exemplify in a word the general purpose of this new monograph on the ancient topic of epilepsy. Dr. Pagniez, roaming over a literature, old and modern, of incredible abundance, has aimed at selecting what seems to be of significant value from the double standpoint of pathogenesis and of treatment. In respect of the former, we cannot say that he has succeeded in closing discussions that seem interminable, but he has accomplished a useful and laborious task in presenting the reader with a clear description of rival theories and in underlining what in his opinion merits attention. Through his mind various hypotheses have been submitted to critical sifting as far as their evidential bases are concerned, and in this sense he has lightened the work of the newcomer to the study of epilepsy. Apparently Dr. Pagniez is impressed by the researches now in vogue which bear on the chemical, biochemical, and humoral side of the subject, and we are not sure that he has presented the arguments for the neural or neurogenic view as favourably as might have been done. Still, those who read his book with mental detachment must allow that a unitary explanation of epileptic pathogenesis is scarcely admissible so far as contributory factors are concerned, even though the crux of the interaction of vascular and neural elements remains. The treatment of epilepsy is open to the criticism of being incomplete. Every practitioner must have been conscious of this imperfection at one time or another; if he forcibly reduces seizures by strong sedatives he is aware of the essential crudeness of the proceeding; if he is delighted by operative success along surgical or humoral lines he cannot deny their inapplicability to other instances of the affection.

When all is said, it is something to know that the road is being cleared for further systematised attack on these difficulties, and Dr. Pagniez undoubtedly helps to show the way.

WOOLWICH MEMORIAL HOSPITAL.—An annexe to the maternity ward and a bed, endowed by the London committee of the Remembrance League, were last week accepted and handed over by the Duchess of Atholl, who also unveiled a commemorative tablet. The hospital was built two years ago at a cost of £250,000.

THE LANCET.

LONDON: SATURDAY, MARCH 8, 1930.

PROTECTION AGAINST MEASLES.

CONVALESCENT measles serum is being widely employed throughout Europe and America and, as we are reminded by Dr. W. A. LETHEM,[1] in many places steps have been taken to organise the supply and distribution of the serum, while in some it is scheduled in the local enactment corresponding to our Therapeutic Substances Act, so that the sterility of the prophylactic may be guaranteed. In this country the method has not been widely applied outside certain of the infectious and children's hospitals, and this is almost entirely because of the difficulty of getting supplies of the serum. Even in hospitals this difficulty may be acute, for it is not always expedient or practicable to take blood from the small children who form the bulk of measles patients, whilst adults, somewhat scarce in hospitals and fresh from a sharp illness, cannot always be persuaded to be bled for the benefit of all and sundry. The results of the schemes started in some of the London boroughs to secure supplies from adult measles patients, treated at home and brought to the notice of the health department by the practitioners, will therefore be awaited with interest. The suggestion has been made, and there is much to commend it, that the chance of such schemes succeeding would be increased by payment of the donors. Such payment need not involve great expenditure to the health department, which could recoup itself by making a charge for the prophylactic dose. But even with careful management, and alertness in finding sources of supply, it is doubtful if a reserve could be maintained sufficient to meet the current needs of epidemics so widespread as measles. Fortunately, the supply of donors of this precious commodity is not limited to those who have recently passed through an attack of the disease. The solid immunity engendered by an attack of measles is reflected in the rarity of second attacks, and there is little reason to doubt that this immunity is the result of the persistence of antibodies well into adult life. This fact was taken advantage of by DEGKWITZ[2] as long ago as 1920 in the production of passive immunity to measles by the injection of serum from adults who had previously suffered from the disease, and his observations have since been confirmed by various investigators. This important fact had apparently become submerged, but we now have timely reminder of it by the appearance of reports from Dr. E. H. R. HARRIES,[3] of Birmingham, and two pædiatricians of Philadelphia, Dr. A. E. SIEGEL and Dr. H. ERMANN.[4]

Dr. HARRIES's report is the more circumstantial, and the details are of considerable interest. A supply of pooled serum was obtained from 11 or 12 probationers who had a definite previous history of measles in childhood, and was put up in 10 c.cm. doses. Fourteen susceptible children each received a dose on the seventh day following exposure to measles, and two developed attenuated measles after a long incubation period. In three other exposed ward populations a similar procedure was adopted on the day after exposure, but no measles occurred among the 40 children injected. One of the exposed patients, however, had been removed from one of the infected wards on the day of exposure, but on account of having a previous history of measles did not receive an injection; as evidence that the exposure was effective it is noted that this child developed measles. Further injection of the contacts of this case on the day after exposure was followed by no further appearance of the disease. Dr. HARRIES, in his inference that the pooled adult serum was the predominating factor in suppressing these outbreaks, rightly stresses the importance of the attenuated cases. The Philadelphia work relates to an experiment carried out in a home in which there were 100 children. Measles appeared, affecting 10 of these between March 24th and April 11th, 1928, and two batches of 35 and 20 children unprotected by a previous attack were given 5 c.cm. of a pooled adult serum obtained from the parents with a definite history of measles on April 15th and 22nd respectively. The first batch contained those in closest contact with the cases and the youngest inmates. No further case of measles developed although the children went on attending schools in which the disease was epidemic; but rubella appeared between April 23rd and May 1st in 18 children. Of those developing rubella, 10 had received the serum, 6 had not, while 2 were among the original cause of measles occurring in the institution. Whilst it is difficult to evaluate the results of this experiment because of the outbreak of rubella—some of the cases of which in the injected patients may have been modified measles—and also because the adult serum was given late in the exposure, and in smaller dosage than that hitherto considered necessary for protection, there can be little doubt about the efficacy of the serum in Dr. HARRIES's experiment.

The importance of this work lies in the fact that it brings the sero-prophylaxis of measles within the range of measures practicable to the family doctor, for one or other of the parents is almost certain to have had measles, and thus a donor is immed
available. Further, as F. L. BIVINGS[5] has p
out, a parent would always be willing to give
for his own child, and no Wassermann re
should be required. The operation could be re
to its simplest dimensions by the practitioner
drawing 20 c.cm. of whole blood from the
basilic vein of the parent and injecting it
intramuscularly or subcutaneously into the
was intended to protect. It is true that
injection of whole blood produces a hæm

undergoes absorption in the ordinary way, and it is not to be supposed that temporary æsthetic objections would over-ride the solid benefit obtained by protection against measles.

◆

DOCTOR AND PATIENT.

Is the doctor to be the sole judge of the number of visits which the patient should receive? To this question, as indeed to many others, the law seems to answer "Yes and No." A patient underwent an operation which, in view of his general health, was serious; he was three weeks in a nursing home, and apparently left it contrary to the doctor's orders. Sued at the West London County Court for the balance of fees due for professional services, the patient said he had expressed the desire that the doctor should not call so frequently. His Honour Judge Hargreaves did not accept this as a valid defence. "It must be for the doctor," he said, "to decide how often he ought to see a patient." At some stage of the convalescence, the personal relations between doctor and patient ceased to be entirely happy. The patient then wanted to see less of the doctor; he did not actually terminate his contract with the doctor, but he said he was willing to take the risk of reduced attendances. As the learned judge observed, the personal relations between the parties had nothing to do with the matter so long as the professional relationship of doctor and patient continued. The doctor had not chosen the patient; the patient chose the doctor.

At this point the law has satisfactorily answered "Yes" to the question whether the doctor is the sole judge of the number of visits to be paid. Common sense would agree. It is sometimes said that a man who is his own lawyer has a fool for a client; a man who is his own doctor is in much the same position. The contract between doctor and patient is an implied contract; the doctor is to render professional services and to receive reasonable remuneration. The contract must surely assume that the rendering of skilled services is not to be obstructed by the patient's pique or perversity. Though the patient can break off the contract entirely, he can hardly dictate the manner of treatment while the contract endures. But, having answered "Yes," the law now adds "and No." Judge Hargreaves, who has already laid down that it must be for the doctor to decide how often he ought to see a patient, deducts five guineas from the plaintiff's claim because "I have come to the conclusion that after March 7th attendances might have been fewer than they were." The patient had said so, and the patient, it seems, knows better than the doctor after all.

Nor is this the end of our perplexities. According to His Honour's judgment, after the patient had intimated that he was prepared to run the risk of fewer attendances, "the doctor could then, to cover himself, have written a letter to say that the risk of less frequent attendance must be borne by the patient." The purpose of such a letter, presumably, is to furnish prospective evidence for some subsequent tribunal. If the doctor reduces his attendances and the patient dies, the doctor will be able to flourish a copy of the letter in the face of the coroner. Or if an action of negligence is instituted, with allegations of carelessness and inattention, the letter may again be useful. But medical practice cannot be conducted in an atmosphere of lawyers' letters. The doctor must have a free hand in rendering professional service; he does not ask for more than the lawyer himself would claim.

THE EVOLUTION OF IMMUNITY.

The capacity to develop antibodies in response to the stimulation of an antigen is shown to any considerable degree only in birds and mammals. Cold-blooded vertebrates and invertebrates may occasionally be found to give a weak reaction, but there seems no reason to doubt that the antigen-antibody reaction, as we know it in the higher animals, is a comparatively recent achievement of evolution, phagocytosis being the fundamental method of defence which is found throughout the whole animal series. Correspondingly, it is doubtful how far individual acquired immunity plays a part among the lower animals in maintaining the different species against their several parasites. It seems possible to immunise the caterpillars of certain moths against bacterial infections by inoculating them with dead bacilli, but as far as we know the immunity of invertebrates is generally a racial immunity achieved by selection among populations with high capacities for rapid multiplication of the resistant survivors.

This evolutionary history is to some extent recapitulated in the development of the individual as is pointed out by Dr. E. Grasset in an interesting paper.[1] Chickens in the egg, which are very susceptible to the poisonous action of unmodified diphtheria toxin, show no response to repeated doses of toxin detoxicated with formalin (anatoxin), nor does this treatment enhance their capacity to respond to doses of the antigen given after hatching; they neither develop antibodies nor do they become immune. New-born chicks also have little aptitude for active immunisation and their capacity to respond to an antigen appears only after many weeks; adult fowls respond quite well. Young rabbits and guinea-pigs show the same relative incapacity and new-born infants also respond badly to, for instance, diphtheria anatoxin. In the natural course embryos seem to have no chance of learning the antigen-antibody response, because the placenta is not permeable to foreign proteins. This state of affairs would obviously land new-born mammals into a disastrous predicament on their arrival into a parasite-infested world, if no way round had been discovered. New-born children are in fact more resistant to infectious diseases in general than they are a year or two after birth; this protection is obtained by passive immunisation with their mothers' antibodies. This transference may take place across the placenta which, in man, is permeable to antibodies; the fœtus of a typhoid-infected woman may contain typhoid agglutinins. But in other animals (cow, sheep) antibodies will not pass through the placenta, and they are transferred from mother to young by the milk and especially by the colostrum. In adults the oral administration of antitoxins is idle; they are destroyed by digestion and are not absorbed except perhaps in minimal traces. By a merciful dispensation the alimentary tract of new-born animals is permeable to antibodies for a few days after birth, and during this period the young get enough to tide them over till they have developed the ability to make their own. As Theobald Smith showed, the infectious mortality among new-born calves is dreadful if they are prevented from having their normal quantum of colostrum; the mother's blood does equally well.

More recently T. Dalling has demonstrated how effectively lambs may be protected against *Bacillus welchii* infection, which is the basis of lamb dysentery, by vaccinating the mothers with *welchii* toxin; the antitoxin made by the mother is passed on to the lamb in the milk during the first day or two of life while its alimentary tract will absorb it. Similarly, Dr. **Grasset** suggests that in the East and in certain parts of South America, where the neonatal mortality from tetanus may be as much as 20–30 per cent., it would be worth while to inoculate pregnant women with formalised tetanus toxin.

MODERN INDUSTRY AND SCIENTIFIC METHOD.

Modern industry is built on foundations of scientific research devoted to improving the technique of production. Process after process comes into existence in the ever-elastic capabilities of the human race; variety and complexity ever increase and demand proportionally greater intelligence among the workers. Monotonous repetition processes are but temporary expedients until ingenuity has developed machinery to supplant the human hand, and the intricate accuracy demanded to-day from skilled operatives has never before been approached in the history of the race. Thus has industry developed; thus must it continue to develop, if it is to serve faithfully the community to which it owes its existence. And that community which can best supply industry with the intelligent service which it needs must ever move in the van of progress, or, failing, fall back. More and more is it being perceived that the supply of this intelligent service cannot be left to fortuitous circumstance, but that organised research must be devoted to its up-keep. Thus a new science to-day is springing up aimed at detecting both the capacities, needed by industry, innate in each, and the environment of work which is best suited to the exercise of these capacities.

The economics of high wages have driven America forward in the study and practice of this young science, so that both worker and work may be worth the wages paid. In our own country, where modern industry was invented, we are becoming fully aware of the national importance of, and even need for, similar intensive consideration; but our knowledge, founded on research, is decidedly ahead of practice. Two bodies are interested in this situation and are working in close collaboration—i.e., the National Institute of Industrial Psychology and the Industrial Health Research Board. The Board is an official body, the outcome of a war-time perception that industrial health is the basis of national productivity; its efforts are directed to elucidating the principles which guide the human factor in industry. The Institute is a separate concern, paying its way from fees received for services rendered to industrial establishments, but making no profits. It enables individual firms to benefit from putting into practice new knowledge. The work of the Institute during the past year, as gathered from an interesting report for 1929, just issued,[1] includes careful investigation of various industries, and makes many suggestive recommendations for their improvement. The investigators aim at reducing the cost of output by improving machinery, lighting, and the arrangement of workshops, and by distributing the work in such a way as to diminish the fatigue of the workers. Expedition in the work of the coke-loading department of a gas-works has been attained by the employment of an emergency gang of workers which can be summoned at short notice, by an improvement in the type of loading mouthpiece used, and by provision for quicker communication between the heads of departments concerned. In a railway service advice has been given on the improvement of illumination and drainage, and on better methods of storage; changes in the work on automatic lathes have been introduced, which have reduced the costly waste of oil. In some lead works, and in a textile machinery factory, transport was the main problem; in the first case it was expedited by the use of mechanical methods of loading, and in the textile machinery factory a reduction of 40 per cent. in costs was obtained by reorganisation of the transport service under an office and foreman, by some structural alterations in the building, and by the provision of a bonus system for the workers. The introduction of "rest pauses" has been effective in increasing the output in some industries, and in cases where skilled labour is employed schemes to reduce the labour turnover have been put into operation, with good results. The investigations of the Institute have been carried on in cotton doubling mills, telephone and cable factories, cutlery factories, radio and chemical works, iron foundries, and the General Post Office, usually with a resulting increase in efficiency.

Vocational guidance of workers by advice based on psychological tests is still in an early stage of its development, though the members of the Institute place an increasing reliance on the results. During the past year a large number of "performance tests" have been devised which can be applied without the intervention of oral or written language. Some of these appear to have been of value in estimating calmness under pressure, perseveration, and other mental characters, but the Council of the Institute, in the annual report, stresses the need for further research. The value of using tests carefully selected for disclosing aptitudes when engaging new workers is shown. In one case labour turnover, that bugbear of employment, fell from 28 to 15 per cent.; in another case turnover, due to unsuitability, fell from 20–25 per cent. to 1–5 per cent., while the cost of training in the factory was reduced from £31 per head to below £5. In a haulage employment factory we read of movement studies of the processes involved in the preparation of raw material which resulted, from improved working methods and reallocation of workers, in an increase in output of 33 per cent.; we learn of organisation in the polishing and stropping of razors increasing output by 78 and 28 per cent. respectively; of £1600 saved per annum in the interest on capital locked up in materials in process from studying the transport problems of a machinery factory; and of instance after instance where examination of working conditions enabled existing congestion, strain, and irritation to be abolished. Meanwhile, research is being pursued in the vast field of vocational guidance and selection. For example, the after-careers of 1200 London school-children are being followed up; in certain rural and urban schools in Fife the growth of abilities in 472 children between the ages of 11 and 14 is being tested with special reference to choice of occupation after a survey of the local industries; while two other investigations are in progress in Birmingham, in one of which four groups of over 400 boys are being tested to detect innate aptitude for mechanical work. How best to mate the worker and his work is the motive of all these investigations, and the increase in output, brought about implies both better and cheaper production. A new impetus to the driving power of the eighteenth century discoveries is arising, an impetus coming from that right study of mankind—man.

Annotations.

"Ne quid nimis."

PHARMACOLOGICAL RESEARCH.

THE fourth annual report to be issued by the Pharmacological Laboratories of the Pharmaceutical Society of Great Britain is a record of valuable work divided, as in previous years, between research and the examination by routine methods of samples submitted by manufacturers. In the Pharmacological Department much of the work has been on problems arising out of the revision of the British Pharmacopœia. The extract of the posterior lobe of the pituitary gland has been investigated to determine how far the different properties of pituitary extract are present in the same proportions in different commercial samples, and the general conclusion reached was that it is not safe to infer the value of any property from the value determined for another property. Vasopressin and oxytocin, the two constituent parts of pituitary extract, have also been examined, and the fact that the antidiuretic and anti-insulin properties are almost exclusively possessed by vasopressin has been confirmed. It is curious that while it has long been the practice of many firms to submit tinctures of digitalis and of strophanthus for biological standardisation, it has not been the practice to submit samples of strophanthin. A series of commercial samples of strophanthin has been examined to determine their relative potency, with the result that out of nine samples the weakest had only 41 per cent. of the activity of the strongest. This is rather startling in view of the facts that strophanthin is intended for intravenous injection and that the dose is so small. It would appear to be much safer to employ the definitely crystalline glucoside ouabain, which is used as an international standard. The stability of extracts of ergot varying in strength from 35 to 75 per cent. has been tested; these extracts show a loss of activity on keeping so rapid that half the activity may be lost in two or three months even under the best conditions, while at low temperatures the loss is even greater. Concentrated extracts are more stable, but they also lose activity at a rate which appears to vary considerably in different samples. At the request of the Pharmacopœia Commission the toxicity of various commercial samples of tetraiodophenol-phthalein sodium (used for cholecystography) has been tested, the determinations being made by intravenous injection into the tail vein of mice. The dose of each preparation causing death of 50 per cent. of mice within three days was taken as a measure of the toxicity. This dose varied from 0·27 to 0·37 mg. per gramme weight of mouse in seven samples prepared by different makers. In the Nutrition Department some evidence was obtained of the existence of a further factor necessary for the growth of the rat; incidentally the unsuitability of the "vitamin-free casein" for use in tests for vitamin B has again been demonstrated. "Light white casein" should be used in basal diets composed for this purpose. Many observations have been made on the relation of vitamin A to the œstrus cycle, and on the variation of vitamin D in cod-liver oil and in irradiated milk. The number of publications, 17 in all, issued from these laboratories during the year, and their importance, indicate an activity of which the Director, Dr. J. H. Burn, and the Council of the Pharmaceutical Society may well be proud.

ABSCESS OF THE LUNG.

ON Feb. 25th the Section of Medicine of the Royal Society of Medicine discussed the *treatment* of abscess the lung, and various communications illustrated great advances in intrathoracic surgery to which R. A. Young the President, referred in his opening remarks. In skilled hands there is but little more danger in opening the pleural cavity, either for exploration or in order to deal with neoplasm or some suppurative condition, than in performing an exploratory laparotomy. An abscess in the lung may result from many causes, and if it is associated with gangrene, carcinoma, or other gross disease, the results of treatment must always be bad. In the single abscess, which is not infrequently seen after operation on the nose and throat, especially after tonsillectomy, the result of surgical treatment is very satisfactory. It is generally agreed that the best treatment when the abscess has once definitely formed and has failed to improve under expectant treatment is rib resection and drainage. It is essential, however, that the visceral pleura over the region of the abscess should be adherent to the chest wall, and for this reason the operation is usually performed in two stages, the first being to secure the adhesions. If this is not done pyothorax is likely to occur and add considerably to the gravity of the case. For the same reason exploratory puncture should be avoided in a case of abscess of lung and the abscess should be localised by radiography. Pyothorax is especially likely to occur if artificial pneumothorax is induced, and this is now considered to be dangerous and bad treatment except possibly in the case of an abscess situated near the root of the lung and communicating with a bronchus. Many cases of abscess heal spontaneously and in the early stages it is customary to treat the patient by simple medical means, but while it is difficult to judge when medical treatment should end and the surgeon should be called in, there is no doubt that these methods are often carried on far too long. The present policy of waiting to see whether the abscess is going to increase, become chronic, or heal seems unsatisfactory. Good as the results of surgical drainage are, one cannot help feeling that in many cases energetic treatment in the early stages would have prevented the necessity of any surgery at all. It is in the early stage, before adhesions have formed, that pneumothorax is comparatively safe and may prevent the abscess from spreading in the lung tissue. Aspiration through a bronchoscope has been practised in certain cases in the early stages, especially in America, and this method of treatment may lead to an early cure and has not the same disadvantages as artificial pneumothorax. Simple medical treatment so often fails to check the spread of the abscess in the lung that it is in this early stage that we may look for advance in treatment, either medical or surgical.

OCULAR LESIONS PRODUCED BY NAPHTHALENE.

AT a meeting of the Ophthalmological Section of the Royal Society of Medicine last summer the unusual spectacle was seen of a number of rabbits exhibited for ophthalmoscopic examination to demonstrate the ocular lesions produced by the administration of naphthalene by way of the stomach. The exhibitor was Miss Dorothy R. Adams, who publishes further details on the subject in the February number of the *British Journal of Ophthalmology*. The research was carried out for the Committee of Vision of the Medical Research Council at the Department of Physiology, University College.

Naphthalene cataract has been the subject of experiments in laboratories abroad for the last 40 years. Earlier observers were of opinion that it was entirely due to a disturbance in the ciliary secretion, but much investigation has failed to find any confirmation of this hypothesis. The first noticeable changes after the administration of an initial dose of 3 g. of naphthalene to a rabbit are usually what look like exudates and early peripheral lens striæ. On microscopical examination of the retina at this stage the affected areas in the retina prove to be localised patches of œdema without any albuminous or cellular exudates. The œdema of the retina is rapidly followed by atrophy, and in a week or ten days it may become detached with horizontal splits. Degeneration of other tissues of the eye follows. The changes observed in the lens agree with those described by previous observers. An initial swelling is followed by the formation of radiating striæ or fluid vacuoles at the periphery. In two or three days the lens fibres themselves become opaque, first in the posterior cortex and then in the anterior, the cataract becoming complete in about 14 days. A further phenomenon seen in two or three weeks as the result of repeated small doses of naphthalene is the deposition of crystals in the vitreous and anterior layers of the retina. With doses of 0·5 to 1·0 g. daily to a rabbit weighing 2 or 3 kg. or in certain animals of larger size with a daily dose of 3·0 g., these crystals are seen in two or three weeks, or in the case of the larger doses earlier. The crystals seen with the ophthalmoscope are very like synchisis scintillans. Chemically tested, they appear to be crystals of calcium oxalate. With these comparatively small doses the animals are always healthy and undisturbed by the naphthalene, the lens remaining quite normal. Even in the cases with the ocular lesions that result from larger doses the animals remain healthy as a rule, though a young animal may show toxic signs which occasionally cause death before the eyes are affected.

Taken together, the ocular lesions present features which suggest that they may all be due to a disturbance in the normal balance of the inorganic constituents of the body, rather than to any direct toxic effect of naphthalene or its derivatives. It is highly desirable that further research on the biochemical changes that may affect the structures of the eye may be continued, with a view especially to discovering any bearing they may have on senile cataract in man.

THE VITAMIN VALUE OF FOODSTUFFS.

A FULL index of foodstuffs, in which a numerical value for each vitamin is ascribed to each article of diet, could not be compiled on our present knowledge. At present it is not possible to make more than a rough grading, by using one to three crosses, as was originally done in the Medical Research Council's Report [1] on Accessory Food Factors. This was last brought up to date in 1924. Since then more knowledge has been accumulated, more foodstuffs have been tested, and the grading is somewhat more precise. Doubtless the new edition of the Report now about to be compiled will record these advances. Meanwhile a useful publication,[2] bringing the position up to date, has just appeared over the name of Sybil L. Smith, Senior Chemist to the Office of Experimental Stations, United States Department of Agriculture. This little handbook contains a very short, concise and accurate account of each of the vitamins and full tables of the vitamin values of foodstuffs, compiled from all available sources. It also includes a bibliography of the literature from which the tables have been made, and another bibliography of the technique of testing for each of the vitamins. Until sets of tables with numerical values can be put out, this pamphlet will be of the utmost value, not only to the scientific worker but also to all those who are responsible for planning dietaries, whether in institutions or in the home, whether for human beings or animals. The possibility of compiling tables with numerical values is not, perhaps, quite so very remote. The initial difficulty lies in the provision of a pure standard of constant biological activity, with which all unknown substances can be compared. It seems likely, for example, that a preparation of irradiated ergosterol can be made constant, and if so, a certain unit of the preparation should be able to supply a practical standard for vitamin D. Such a standard is, indeed, already in use by the Pharmaceutical Society of Great Britain in their vitamin testing department, and has been found to work well. As for vitamin A, if preparations of carotene of a certain degree of purity are found to have a constant value for biological activity, the provision of a standard here may be found before long not impossible. The other vitamins offer no such hope at present.

BACTERIOPHAGE AND LYSOGENIC BACTERIA.

IT has long been known that under the influence of the bacteriophage certain strains of bacteria develop which contain this principle in symbiosis. Some of these organisms undergo lysis and form worm-eaten or nibbled colonies, but others show no evidence of the associated bacteriophage except by their action on other species of bacteria. The nature of this stable condition, whereby organisms can harbour the lytic principle without themselves undergoing lysis, is of much interest. J. Bordet and F. Renaux [1] think it is dependent upon a balance between the bacteria and bacteriophage; a small number of the former are constantly undergoing lysis, and this maintains the activity of the principle, which (it is generally agreed) is only produced during the multiplication of the organisms. According to this view the resistance of the lysogenic strains is more apparent than real.

F. M. Burnet and M. McKie [2] have been studying such a lysogenic strain of *Bacillus aertrycke*. From the parent strain, which was rough and motile, they prepared the common rough and smooth variants, and found that whilst all of them were lysogenic for the test organism—*B. sanguinarium*—the rough types were generally much more active than the smooth. They further tested a very large series of the less common variants, comprising most of the variant types which have been described in the salmonella group, and here also they found that every type of variant was lysogenic. They accordingly conclude that the property of lysogenesis is a possession of each and every individual in a lysogenic culture and one of its essential properties. The fact that the R forms were the most actively lysogenic, whilst the particular phage showed no action on any rough strain of sensitive organisms is, they consider, an argument against the view that a non-detectable form of lysis is always going on in the lysogenic strains. They postulate that the phage, or its precursor, is present in every cell of the lysogenic strain of bacteria, and that it may be liberated during the process of growth. They find, however, that while it may be extracted by certain procedures from the non-multiplying cell it is not liberated by others which undoubtedly disrupt the cell. They assume that the difference depends upon whether the phage is present in an active condition or as an inactive precursor. By such a conception of a dual state they believe that the parasitic view of the bacteriophage can be reconciled with the view that it is a pathologically altered constituent of the normal cell. As such it remains latent, and is to be regarded as a component of the cell; but after activation and liberation—which appear to take place inside the cell—it shows its presence by a predatory parasitism on sensitive cells. This is the aspect which has been prominent in most observations.

Another interesting investigation of the bacteriophage has been made by I. Dresel and M. R. Lewis.[3] As is well known, large claims have been made by d'Herelle and his associates for the destructive powers of the bacteriophage upon bacteria in the body. A regular school of therapeutics has been built upon this effect. The resultant controversy has led Dresel and Lewis to study bacteriolysis in tissue cultures, in an endeavour to determine whether under these conditions infecting organisms can be destroyed by the lytic principle. Their results may be briefly summarised as negative. Neither in the presence of the growing cells of an animal peculiarly susceptible to the infection (mouse typhoid), nor in the presence of cells of an animal normally resistant to the infection, did the presence of added bacteriophage influence the noxious action of organisms upon the growing cells. In the case of resistant tissues the growth of leucocytes delayed the proliferation of the organisms, the liquefaction of the culture plasma, and the destruction of the culture; but this was an effect solely attributable to the type of tissue in use, and was in no way modified by the presence of bacteriophage.

HOSPITAL MEETINGS AND HOSPITAL REPORTS.

AT this season of the year a large proportion of the provincial voluntary hospitals are holding the annual meetings of their supporters. The broad impression left by the proceedings at these meetings, and the more or less detailed accounts of their work during the past year, is one of abounding activity and improved finances. There are still, no doubt, many instances of expenditure exceeding income, but there are far more in which there are favourable, if usually small, balances. Looking at the rapid and severe growth of the pressure upon the hospitals, it is rather remarkable that there should be any surpluses anywhere, and their existence is not the least conclusive proof of the resilience of the voluntary principle. Almost suddenly the country has begun to acquire the hospital habit, and the realisation that hospitals are no longer merely refuges for the sick who cannot afford prolonged medical or surgical attendance, has, in more ways than one, created difficulties which are being courageously met. Thus the "pay bed" is rapidly becoming an institution, and the hospitals contemplating, or actually making, enlargements, are to be counted by the score. A few years ago the confidence with which huge expenditure in buildings and equipment are undertaken would have seemed almost criminal lightheartedness. But the pressure upon beds and out-patients' departments has got to be met if the whole system is not to break down. It could not possibly have been met had the hospitals still been dependent, in the main, upon voluntary subscriptions and upon endowments which, save in the case of a comparatively few great and old-established ones, are more or less negligible. The masses have been called in to redress the balance of the classes, whose help has, perforce, become almost stationary. Contributory schemes, with membership ranging from a few hundreds to many thousands, are arising on every hand, and, so far as we are aware, not one of them has failed in its object. Here and there a hospital board had held back from timidity, but it is a fairly safe prophecy that eventually nine-tenths of the genuine hospitals will derive a large proportion of their revenue from the pence of the working-classes. From the point of view of medical and surgical science, the information derived from these annual meetings is full of encouragement. Everywhere there is the same story of increased and improved equipment, and of the adoption of means, nearly always costly, of alleviation or cure, not primarily dependent upon drugs. Massage and radiological departments, and provision of the many varieties of electrotherapeutic treatment are demanded all along the line, and accommodation is being rapidly increased. The virtual unification of our hospital system is coming not a day too soon. The death of the poor-law hospital means new life for the voluntary hospital, because it means, to use the current shibboleth, something in the nature of rationalisation. To what extent the public assistance hospitals will relieve the pressure upon the voluntary institutions time alone will show, but we know enough to be sure that, for the present, at all events, the relief will not [illegible] be appreciable, but that it may reasonably be [illegible] to facilitate that specialisation which has hitherto been seriously limited by circumstances.

In view of the great changes that are about to occur, it is of increasing importance that all hospitals, large or small, general or special, should issue their detailed printed reports with far greater promptitude than hitherto. It is a duty which they owe to each other as well as to their individual supporters. Hospital management has become a science, and a comparative study of these reports is of real practical value. The system of hospital accounts has been standardised, and something more in the nature of the standardisation of information is highly desirable. The cost of beds and of patients' maintenance in two, or half a dozen roughly comparable hospitals, may and does differ, and managers and secretaries may well be anxious to ascertain why the cost is greater in one case than in another. A study of these reports should help, but the help will be minimised if the information, when it becomes available, is six or more months in arrear. Stale statistics are often misleading, and hospital comity demands that the interchange of such-like information should be not only lucid but prompt.

GRASSUS ON THE EYE.

THE little text-book on the eye by Benevenutus Grassus of Jerusalem, which Dr. Casey Wood has translated,[1] was for more than 400 years the most popular of ophthalmic manuals. When the first manuscript was written, and in what language it was composed, is not definitely known, but the earliest manuscript existing is the thirteenth century Provençal codex now in the library of the University of Basel. Dr. Casey Wood states that there are about 40 texts extant, 22 in manuscript and about 18 printed editions. The Ferrara edition (1474 A.D.) ranks among the true incunabula. The exact date of publication may be a matter for dispute, but Dr. Casey Wood advances convincing arguments for placing it in 1474. Curiously enough another work with an ophthalmological title—the *de Oculo Morali* of Archbishop John de Peckham—was published by Anton Sorg, of Augsburg, in the following year; this latter work makes no pretence to being a practical ophthalmic manual. Peckham was a noted mathematician, possessed of a knowledge of optics, considering the age in which he lived, unsurpassed save by that of his fellow Franciscan, Roger Bacon; but Peckham was not a medical man and in the *de Oculo Morali* the eye serves "as a peg on which to hang saintly saws and religious dogmas."

No one can read this little book by Grassus without realising that it is a really practical work; regard is continually being paid to the general condition as well as to the local ocular state, and clear rules of regimen are laid down when these are indicated. In those early days the only surgical treatment for cataract was couching; Grassus distinguished seven kinds of cataract, of which four were curable and three incurable, and he reminds his readers that if any are so minded as to attempt a cure in unsuitable cases they will labour in vain. In couching, the advice is given to depress the cataract from the pupil, pushing it well down and holding it down "until you have said four pater-nosters." Under the title "scabies of the eye" a good description is given of trachoma, the mechanical ptosis being noted; on everting the upper lid the inner surface is found to be thickened, "with granular deposits in its substance like grains of millet." In the treatment of this condition, after a suitable purge, we are told to "evert the diseased lid and squeeze out the fleshy growths with the fingers, aided by the knife, attacking first the parts towards the inner canthus, finally removing all the granulation tissue beneath the lids. Then place cotton-wool moistened with white of egg on the eye as a dressing for fifteen days, after which my *emplastrum gratiosum* should be applied twice a day for three days. The patient may then open his previously useless eyes." The use of the Alexandrine collyrium completes the cure. It is interesting to find that Grassus recognised the connexion between *muscae volitantes* and black bile. This work also contains a good account of pterygium and its surgical treatment. The topical applications seem for the most part to be bland and unirritating; the nasty messes which formed so great a part of the therapeutic armamentarium of the Middle Ages are absent, and there is no reason why Grassus's apple poultice should not be as good an application for a stye as many other dressings which have been recommended in modern times. Only eight copies of this 1474 edition of the work appear to exist; three are in America, the Pierpoint Morgan copy having been bought from an English sale as recently as 1905; four copies are on the Continent, two in the Bibliothèque Nationale at Paris, one each at Rome and at Naples; and one copy is in the library of the Royal College of Surgeons of England. The facsimiles of pages of the Ferrara edition, the Provençal codex, and the Ashmolean Old English codex in the Bodleian Library, add greatly to the interest and value of the book.

---

[1] De oculis eorumque egritudinibus et curis. Translated, with notes and illustrations, from the first printed edition, Ferrara, 1474 A.D., by Casey A. Wood, M.D., LL.D. California: Stanford University Press. London: Humphrey Milford, Oxford University Press. 1929. Pp. 101. 23s.

Dr. Casey Wood deserves praise for his translation and for the valuable footnotes identifying the various herbs in use, as well as for his learned preface. The type, paper, and format of the book are beautiful.

POST-VACCINAL ENCEPHALITIS.

REPORTS on post-vaccinal encephalitis in Germany and Sweden are published in the latest *Bulletin d'Office Internationale d'Hygiène Publique* (December, 1929, p. 2052). In the former country during 1927, 1928, and the first nine months of 1929 51 probable cases have been discovered. In these three years the numbers were 16, 21, and 14 respectively and the total mortality was 22. The time of onset after vaccination agreed with the experience of other countries with the maximal incidence on the eleventh day. Forty-six of the cases, with 17 deaths, occurred after primary vaccination and over a million persons were primarily vaccinated each year. Eight cases with four deaths were in children under one year old, and 18 with five deaths between the ages of 1 and 2. It is stated that most children are vaccinated before they are two. In the three years only five cases followed revaccination at ages of 12 to 14 years and all died, but in two of them no trace of primary vaccination was visible, and three of the five were not certainly cases of the disease in question. The revaccinations of children at 12 years during this period were about four million. Most cases occurred in May, June, or October, the numbers being 21, 8, and 6 respectively, and there was no apparent tendency to aggregation of cases into special districts. The figures thus confirm former observations on the rarity of post-vaccinal encephalitis after revaccination and the complication is once more seen to be relatively uncommon when primary vaccination is performed under the age of one. An inquiry in Sweden made in 1929 retrospectively by C. Kling, N. Lönberg, and E. Wassén discovered 20 possible cases, with five deaths during the years 1924–28. These were distributed as 3, 2, 2, 4, and 9 during the five years respectively, and occurred in the proportion of 4·7 per 100,000 vaccinations. Of the 20 cases, seven were believed to be probably not post-vaccinal encephalitis. In the first six months of 1929, following a special request to practitioners, four cases were notified among 45,000 vaccinations. One of these, with onset on the eighth day after vaccination, was probably poliomyelitis and survived with persistent paralysis. Two cases in boys of 6 and 7 years with onset on the twelfth and thirteenth days after vaccination died, and the fourth case occurred in an infant of 7 months, who had convulsions and opisthotonos on the thirteenth day after vaccination but appeared well next day. The post-mortem and histological examinations of the two fatal cases are stated to have shown the typical appearances of post-vaccinal encephalitis. The authors, however, describe rounded or oval bodies, resembling protozoa, in the brain, which they believe to be the causal agent. Cultures gave negative results and animal experiments are now in progress. These "bodies" do not appear to have been seen by the many other pathologists working at this disease. Kling and his colleagues state that during the five years in which the 20 cases of post-vaccinal disease occurred, 32 cases of meningo-encephalitis have been observed following measles, 12 after whooping-cough, 7 after mumps, and also 969 cases of epidemic encephalitis. They consider the evidence is in favour of post-vaccinal encephalitis being due to the lighting up of an infection with a hitherto undescribed micro-organism.

W. Knoepfelmacher[1] gives a valuable review of the whole subject of post-vaccinal encephalitis and discusses critically the various views of its ætiology. The suggestions that the infection is due to vaccinia virus alone in persons of special predisposition, that it is essentially due to the virus of poliomyelitis, encephalitis lethargica, or herpes, either already present but latent, or predisposed to by vaccination—all these present very serious difficulties. A hypothesis that the encephalitis is rather an allergic phenomenon than an infection has very little to support it. The tendency for aggregations of cases to occur in some districts or communities is noticeable. The view which is least at variance with the facts is that put forward in the report of the Rolleston Committee, and by others—namely, that vaccination arouses into activity an infection with a latent unknown virus, and that this virus may be the same as that causing similar inflammation of the central nervous system after measles, varicella, or mumps and in the cases of meningo-encephalitis disseminata described of late years. Knoepfelmacher's prophylactic recommendations are almost the same as those of the Rolleston Committee, with the addition that he suggests further trial of intradermal or subcutaneous insertion of the vaccine lymph.

In the same journal[2] O. Reisch describes a series of eight cases of acute nervous disease observed in the valley of a tributary of the Inn. They occurred among 233 children, aged 5 to 10 years, who had recently been primarily vaccinated. A characteristic symptom consisted of very marked frequent twichings, almost confined to the muscles of the trunk. Two of the cases ended fatally and the characteristic changes of post-vaccinal encephalitis were found in the brain. On examination of 300 children of the district similar myoclonus was found to be present in some degree in a large number, equally among the vaccinated and unvaccinated. Reisch points out that though the symptom was first noticed in cases of severe disease after vaccination it was really due to an epidemic of an independent affection of the central nervous system, but might not have been recorded except for the coincidence of vaccination.

It is of interest to note that Eckstein, Herzberg-Kremmer, and Herzberg[3] have been able to demonstrate the presence of vaccinia virus in the blood of recently vaccinated children—in 8 out of 14 primary vaccinations—especially between the sixth to eighth day after vaccination. The fact that vaccinia virus circulates in the blood and can be recognised with difficulty was already known, as well as the much lesser frequency with which it can be detected after revaccination. Eckstein and his colleagues also sought for the virus 19 times in the cerebro-spinal fluid, but it was only found once, in a case of post-vaccinal encephalitis.

THE INFIRMARY OF THE MEDIÆVAL MONASTERY.

In the course of a lecture delivered at University College, London, on Feb. 21st, Mr. Percy Flemming pointed out that the monastic infirmary was primarily for the use of the old and infirm monks and was not a hospital. It was recognised, however, that the monastic life might be responsible for what to-day would be called functional nervous trouble. Patients of this type from the monastic infirmary at Westminster, with which Abbey Mr. Flemming was specially concerned in his lecture, were sent to take the air and walk in the meadows at Battersea, Wandsworth, or Hendon. Among the more definite ailments from which the monks suffered, judged by the entries in the account books, a disease of the tibia seems to have been common—probably due to excessive kneeling. The cost of treatment for different patients shows that the severity of the cases varied greatly; in some cases it was 3*s.* or 3*s.* 6*d.*, in others 40*s.* for surgical attendance. (These figures should be multiplied by 15 to make them equivalent in value to our money.) As the Westminster monks had only two baths a year and did not completely undress on going to bed, the serious case may well have been due to infection of a simple abrasion. The infirmary was in charge of the infirmareis who was more concerned with administration than with medicine. In addition there was a medical officer who might live in and probably did so at Westminster. In 1351 the medical officer of health of Westminster was paid £2 13*s.* 4*d.* Periodical blood-letting was part of the monastic rule. The operation was usually followed by a short stay in the infirmary, where the patient enjoyed quiet and a better dietary. The water-supply of a monastery was usually taken first to the infirmary block. Westminster received its supply from the springs in Hyde Park, near the present Albert Gate. The last Abbot of Westminster was Feckenham. He wrote a book, which can be seen in the British Museum, under the title (written in his own handwriting) of "A book of sovereign remedies against the most common and known diseases, and that chiefly for the poor which had not at all times the learned physician at hande." This same Feckenham is known to have used his influence with Queen Mary at one time to save 28 victims from the stake. Mr. Flemming, from a survey of his attitude to sick persons and heretics, believes Feckenham to have been a kindly, sympathetic man, worthy of the honour of being the last Abbot of Westminster.

CHEMICAL WARFARE.

In the House of Commons this week Mr. Lawther called attention, by question, to the increased number of applications coming under the consideration of war pension committees where the sufferers attributed their condition to gas poisoning during the war. Reference in the question was chiefly to tuberculous patients, although allusion was also made to neurasthenics, and the object of the question, which was asked in almost similar terms on the same day by Mr. Shepherd, was to inquire whether a special commission could be erected to investigate the period at which, after the receipt of the original injury, tuberculosis might develop. The Minister of Pensions, Mr. F. O. Roberts, said the connexion of exposure to gas and the subsequent development of tuberculosis had been considerably investigated with results which did not justify the inquiry of the kind suggested, while he went on to remind the House, several other members having intervened in what became a short debate, that every individual case of this sort, where gas poisoning could be held to be precedent to the illness, had been and was being carefully considered, the benefit of the doubt being always given to the applicant. Undoubtedly, owever, ground can be made out for particular quiry, for there is evidence from French authorities that the delayed action of gas poisoning in relation to tuberculosis constitutes a real problem. That it should exist nearly 12 years after the Armistice gives weight to the fact that a large number of nations have welcomed the protocol prohibiting chemical and bacteriological methods of warfare. For on the same day, in the House of Commons, it was stated that the following countries have ratified or definitely acceded to the necessary convention: Australia, Austria, Belgium, Canada, China, Egypt, Finland, France, Germany, India, Italy, Liberia, New Zealand, Persia, Poland, Roumania, South Africa, Spain, Turkey, Union of Soviet Socialist Republics, United Kingdom of Great Britain and Northern Ireland, Venezuela, and Yugoslavia. Further, Denmark, the Netherlands, and Portugal intend shortly to ratify, while the United States of America, Czecho-Slovakia, Bulgaria, Japan, Norway, Sweden, Switzerland, and other civilised countries have already signed the convention, though ratification is still awaited from them. The position is, in fact, very reassuring.

APPLES FOR DYSENTERY.

Old popular remedies have a happy knack of turning up again, to the joy of sceptics, cynics, and other non-progressives. The latest revival is the use of apples in dysentery, typhoid, and other acute and chronic diarrhœal disorders of infancy and childhood. Prof. Moro,[1] professor of diseases of children in the University of Heidelberg, recently discovered in an old book that apples were reputed to be a sovereign remedy for these disorders, and set himself to determine what grain of truth might lie in this. Accordingly children with high fever and dysentery, often seriously ill, were given ripe apples mashed into a purée, as much as 20 to 50 ounces daily—equivalent to 7 to 20 moderate-sized apples. Nothing else was given for two days, not even water. After this a diet consisting of stale bread and butter, toast, mashed potatoes, lean meat, cream cheese, bananas, and cocoa was given for another two days, and then the child resumed its normal diet. Fifty-two cases—some frank dysentery, others of non-specific acute and chronic diarrhœas of childhood—were treated on these lines with excellent results; within 12 to 24 hours the fever had fallen, the diarrhœa had stopped, and the child looked well. No bad effect was observed; relapses were very uncommon, and when they did occur were easily cured by another "apple-day." No medicine was given.

Part II. of Mr. Bowdler Henry's article, "The Interpretation of Dental Radiograms" (a contribution to the Clinical Interpretation of Aids to Diagnosis), has been held over this week owing to the mechanical difficulty of reproducing the illustrations.

Dr. Maurice Alan Cassidy, physician to St. Thomas's Hospital, has been appointed physician to His Majesty's household, in succession to Dr. Herbert French.

Dr. Donald Hunter will deliver the Goulstonian lectures at 5 P.M. on March 11th, 13th, and 18th at the Royal College of Physicians of London, Pall Mall East, S.W. His subject is the Significance to Clinical Medicine of Studies in Calcium and Phosphorus Metabolism. Any member of the medical profession will be admitted on presentation of a card.

A Somerset Hospital.—Mr. B. H. Hill recently laid the foundation-stone of a new wing of Paulton Memorial Hospital. The cost of its erection is being borne by the Miners' Welfare Fund.

Special Articles.

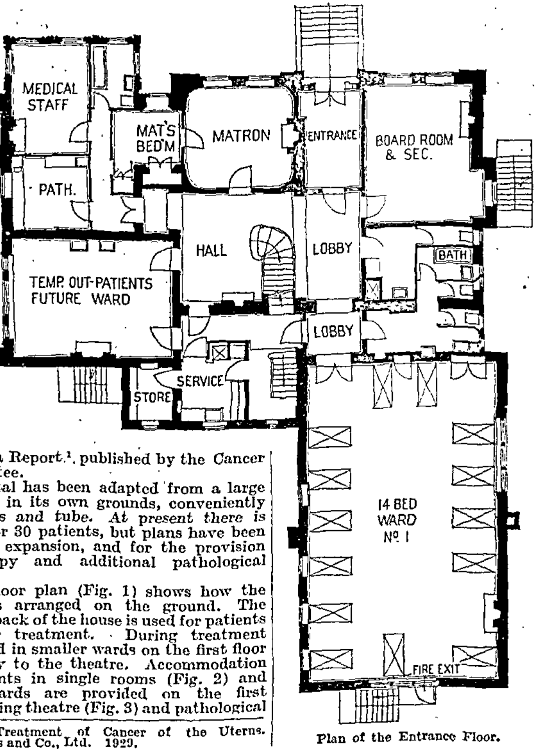
THE MARIE CURIE HOSPITAL.

NEW CENTRE FOR THE TREATMENT OF CANCER BY RADIUM.

THE systematic treatment of cases of uterine cancer by radium has been carried on by the Cancer Research Committee of the London Association of the Medical Women's Federation for over four years. The clinic as originally organised was attached to four hospitals—viz., the Royal Free Hospital, the South London Hospital, the Elizabeth Garrett Anderson Hospital, and the New Sussex Hospital, Brighton—but through the generosity of the public a new hospital, called the Marie Curie Hospital, was opened last August at No. 2, Fitzjohn's-avenue, near Swiss Cottage, London, N.W., *in order that the work might be centralised and* expanded. The four original hospitals still remain in active coöperation, and the staff of the Marie Curie Hospital is mainly composed of medical women holding appointments on their staffs.

Before the clinic began its work in 1925, a careful survey was made of the results claimed by workers at different clinics all over the world. This enabled a decision to be made on the technique to be adopted. In order that the method used might be tested thoroughly in a large number of cases, it was agreed that, while each surgeon should have entire charge of her own cases, the method and principles of treatment were to be settled by the staff as a whole on the advice of the Cancer Research Committee. An account of the inception of the work, of the progress made during the past four years, and of the arrangements for the future is given in a Report,[1] published by the Cancer Research Committee.

FIG. 1.



Plan of the Entrance Floor.

The new hospital has been adapted from a large mansion standing in its own grounds, conveniently accessible by 'bus and tube. *At present there is* accommodation for 30 patients, but plans have been made for further expansion, and for the provision of X ray therapy and additional pathological laboratories.

The entrance floor plan (Fig. 1) shows how the accommodation is arranged on the ground. The large ward at the back of the house is used for patients before and after treatment. During treatment patients are placed in smaller wards on the first floor in close proximity to the theatre. Accommodation for private patients in single rooms (Fig. 2) and double-bedded wards are provided on the first floor. The operating theatre (Fig. 3) and pathological laboratory are fully equipped, and there is a closely organised follow-up clinic.

The Organisation of the Staff.

The scientific advisory council of the hospital are Sir Walter Fletcher, Prof. E. H. Kettle, Prof. Sydney Russ, Sir Charles Sherrington, and Sir Cuthbert Wallace. The research work is carried out under the charge of the Cancer Research Committee, of which the members are Miss M. Chadburn (chairman), Lady Barrett, Miss E. Bolton, Lady Briscoe (secretary), Dr. H. Chambers, Dr. E. M. Magill, Dame Louise McIlroy, Miss L. Martindale, Dr. Kate Platt, and Dr. E. Hurdon, research officer and Director. The medical staff consists of 17 surgeons, five physicians, a Director, a pathologist, and a radiologist. All surgeons on the staff have the right to attend their own cases, irrespective of seniority. Patients not sent in under special surgeons are allocated to surgeons on a rota. The resident staff includes a house surgeon, an experienced matron, three sisters, and as many staff and assistant nurses as are required.

Admission of Patients.—Fees.

Patients are admitted through the out-patient or in-patient departments of the four hospitals mentioned above. Private practitioners who want their patients taken in may apply to any member of the staff, or direct to the secretary at the hospital. Patients may also apply direct to the hospital; and when they do so, the hospital authorities communicate with the private doctor, if there is no valid reason against such a course. A clinic is held every afternoon, in charge of a member of the staff, for diagnosing new patients and examining follow-up cases. Patients who present themselves while the clinic is in progress will be seen then, or will be told when to come again.

Patients in the general ward pay from nothing to 3 guineas a week, according to their means, arrangements being made through the Secretary. Private patients pay from 5 to 15 guineas a week, according to the room occupied. The surgical staff make their own arrangements with the patients regarding fees, and each pays one-third of the fee received to the hospital for the use of the radium, and arranges for the payment of other members of the staff—i.e., pathologist, anæsthetist, or radiologist.

---

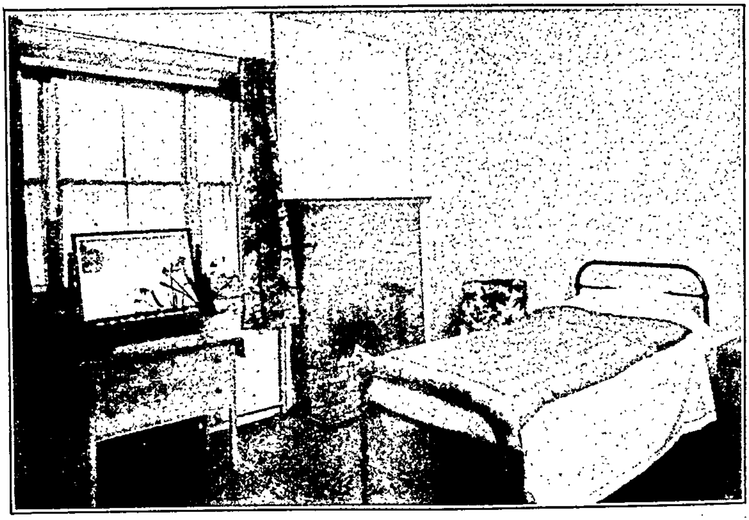
[1] The Radium Treatment of Cancer of the Uterus. London: H. K. Lewis and Co., Ltd. 1929.

Duration of Treatment.

Patients come in two days before treatment, and if not well enough for radium treatment are kept in hospital for tonic treatment. When they are fit, they have radium treatment, and remain in hospital during the following week; if there is no reaction or contra-indication at the end of this first week, the second application of radium is made. A day or two after this second treatment, if conditions are good and the patients are well enough, they go home for a fortnight, and then come back for a third treatment. They leave finally, if fit, about two or three days after this last treatment, and are instructed to attend the follow-up clinic when requested, Arrangements are made for district or private nurses to administer any after-treatment required, usually a douche. Subsequently patients are examined at regular intervals; if they do not respond to letters, they are followed up to their homes by competent investigators, who report to the Director. The Director then communicates with the patient again, and seldom fails to convince her of the need for periodical visits to the clinic.

Post-graduate Courses.—Special facilities can always be arranged for post-graduates requiring instruction in radium application. It is hoped to institute research scholarships, and courses of instruction are already being planned.

FIG. 2.



A Private Bedroom.

Some Results of Treatment.

Over 400 cases of cancer of the uterus have now been treated since the clinic was started in connexion with the four hospitals. The number of cases shown in the last annual report published in 1929 was 322. Only 68 of these could have been treated by surgical operation; the remaining 254 were quite inoperable. Of the operable cases 90 per cent. were free from all signs of cancer when last seen, and nearly all the inoperable cases were materially benefited. Some of them were free from symptoms for many months, some for two or three years. The final stages of the disease in the patients who died were, as a rule, accompanied by much less suffering, because of the absence of local septic conditions. In a few cases there was a recurrence of hæmorrhage shortly before death. Fistulæ, due to extension of the growth, were apparently less frequent than in cases untreated with radium. Death was usually from asthenia due to internal metastases; in four cases it was due to uræmia. Only one death occurred as a direct result of the treatment.

FIG. 3.

The Operating Theatre.

Statistics of the cases treated are being kept in the form advised by the Radiological Subcommission of the League of Nations, so that results can easily be compared with those from other centres in all countries. The first five-year period does not end till September of this year, but the results of a three and a half year follow-up period, though too short to justify deductions, are encouraging.

PARK HOSPITAL, DAVYHULME.—This great poor-law infirmary, near Manchester, was opened in June last by Princess Mary, but although there are 500 beds there were a month ago only 284 ordinary and 13 private patients. Dr. J. J. Butterworth, the medical officer for Lancashire, recommends that it should now be taken over by the county public assistance committee for use as a public hospital. The institution, which is at present under the control of the Barton-upon-Irwell Board of Guardians, and cost £376,000, has all the most modern equipment.

EXTENSION OF LINCOLN COUNTY HOSPITAL.—The Governors have adopted, as an urgent necessity, an extension scheme which, in its entirety, will cost £100,000. Immediate steps are to be taken to raise £45,000, so that the first section of the work may be begun without delay. In the last ten years the demands upon the hospital have nearly doubled, but in that period only 20 additional beds have been provided. The comprehensive scheme includes a new block of two wards containing 50 beds; a new out-patient and casualty department, the present one being greatly overcrowded; a new in-patient unit of 20 beds for eye cases, the increase of which is described as "enormous"; a new operation unit and a larger X ray department. There will also be a new pathological annexe, better accommodation for resident medical officers, and an enlargement of the nurses' home.

THE LONDON HOSPITAL: FREEDOM RESEARCH FUND.

A REPORT of work carried out during the year ending March, 1930, has reached us.

Filtrable Viruses.

Dr. S. P. **BEDSON**, Senior Freedom Research Fellow, has continued the study of filtrable viruses, the two main objectives having been (1) the possibility of cultivating these viruses in a lifeless medium; (2) an understanding of the factors concerned in immunity to virus infections.

Artificial Cultivation.—Although this work is far from complete, some interesting and encouraging results have been obtained. Herpes virus has been used throughout and a medium has been evolved in which this virus will survive for three to four weeks at a temperature of 30° C., whereas the control, consisting of virus suspended in a phosphate buffer, becomes inactive in 24 hours. Both the quality of the "takes" given by these cultures when tested at intervals, as well as quantitative estimation of their virus content, suggest that multiplication of the virus occurs. Evidence in favour of virus growth has not, however, been constantly obtained. The results to date are encouraging and at least as demonstrative of multiplication of virus in the absence of living cells as those reported recently by Muckenfuss and Rivers.[1]

Immunity to Virus Infections.—Much of this work has been devoted to a study of the interaction of virus and antibody "in vitro" using principally herpes virus. It has been shown conclusively that the two unite in the test-tube, and this observation led to a study of fixation of complement. Previous work had given negative and inconclusive results with this immunity reaction, but a satisfactory technique has now been evolved, and the results indicate that specific complement fixation can be obtained with viruses and their antisera. Some of this work has been carried out in collaboration with Dr. J. Bland. Dr. Maitland-Jones has undertaken an investigation of the relationship of the viruses of zoster and varicella by means of the reaction of fixation of complement, preliminary experiments having shown that the serum of zoster convalescents reacts specifically with the fluid obtained from zoster vesicles. The question of immunisation with killed virus has also received attention, and it has been found possible to produce a solid immunity in guinea pigs to herpes virus by means of formalised virus. The formalised virus could not be reactivated by serial passage in guinea-pigs.

The work of Dr. Bedson and his collaborators on psittacosis is familiar to our readers.

Nature of Diphtheria Toxin-antitoxin Floccules.

Dr. S. **CAMPBELL SMITH**, Freedom Research Fellow, has attempted to ascertain the nature of these floccules, mainly by the use of the spectrometer. It has been found that the floccules formed by diphtheria toxin and antitoxin closely resemble serum pseudoglobulin; the ultra-violet absorption curves of the floccules and pseudoglobulin are identical. The amount of protein nitrogen present in the floccules bears a quantitative relationship to concentration of toxin and antitoxin reacting in a balanced mixture. The presence of such substances as normal horse serum and lipoid material in the mixture does not alter the composition of the floccules. It is suggested that pseudoglobulin is the actual antitoxin and that antitoxin is not merely carried down by the protein.

A new photo-electric method of measurement has been devised, by means of which earlier findings on the ultra-violet absorption spectra of the serum proteins have been confirmed.

A pigment has been isolated from diphtheria toxin broth; from its property of fluorescence and from its characteristic absorption spectrum this pigment has been identified as a porphyrin. It fades on exposure to light, the toxin being destroyed at the same time. An attempt has been made to correlate the rate of formation of this pigment with the rate of formation of the toxin; so far, however, no relation has been demonstrated.

Complement Fixation with Vaccine Virus and Antisera.

Dr. J. O. W. **BLAND**, Freedom Research Fellow, has carried out a large number of experiments with virus grown in rabbit tissues (particularly brain) and rabbit sera prepared against such viruses. The results were frequently marred by non-specific reactions. Experiments with vaccinia grown in guinea-pig tissues and with antisera prepared in guinea-pigs have been more satisfactory; vaccinia virus used either in the form of suspensions of tissue, diffusates from tissue or vesicle fluid, has been observed to fix complement in the presence of antisera prepared against virus grown both in guinea-pig tissues and rabbit tissues, including brain. These reactions are specific in the sense that vaccinal antigens will not fix complement with normal sera or sera prepared against bacteria which contaminate the antigens, and that vaccinal sera will not fix complement with antigens made from bacterial contaminants, normal tissues, or tissues infected with herpes virus.

The non-specific reactions obtained when brain antigens are used and the failure of virus-brain antigens to fix complement with vaccinal antisera are being investigated.

Production of Immunity to Vaccinia Virus with Killed Vaccine.

Very little, if any, evidence of immunity was obtained when vaccinia virus, killed either with formalin, heat or phenol, were injected into rabbbits. In guinea-pigs, however, it has been found possible to produce complete immunity to a small test dose of virus, and partial immunity to larger doses. This result is obtained whether the virus is killed by formalin, heat or phenol, and no one route of inoculation appears better than another. The degree of immunity obtained is much inferior to that produced with living virus. Work is now being started with monkeys. The cost of the animals used in this investigation is defrayed by the Ministry of Health.

An investigation is being conducted in collaboration with Dr. **CLARK-KENNEDY**, Dr. **KERRIDGE**, and Dr. **RYKERT**, on the variation in complement content of human serum during shock.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

The Future of the Medical Profession.

THE editor of the *Deutsche Ärzteblatt*, the organ of the Ärzte-Vereinesbund, draws attention to the continued increase in the number of medical students. In the summer of 1929, 15,067 medical students were on the register, as against 9660 in 1927. Of these 15,067, 1457 were in the last year of their curriculum, but 3527 in the first year. The editor says that the profession will soon be drowned in this tide of intending medical men if the flow towards medical study goes on. It is true that university training in general has much increased, but in no other profession has it increased to such a degree as in the medical. The shortage of hospital assistants, to which I have already referred[1] has induced many young men to study medicine. But this shortage is only temporary, and it is too often forgotten that qualified medical men after their assistantship have to wait several years until they are admitted to practise with clubs, under the Insurance Act, and that almost the whole profession depend on such practice for their livelihood. The exclusion of nearly 3000 medical men desiring to practise with the sick clubs is founded on a Government regulation under the Emergency Act of 1923. A provision of this Act gives the Government for a certain time the power to take such measures without passing a special law. As things stand, a medical man must wait three years before being admitted to club practice at his residence and five years if he has come to a new locality. The editor proposes that the number of medical students should be reduced by a new provision that medical men must wait 10 years for their admission to club practice. This provision would not affect those who are already students.

---

[1] Proc. Soc. Exp. Biol. and Med., 1929, xxvii., 129.

[1] THE LANCET, 1928, ii., 820.

Serotherapy of Scarlet Fever.

Dr. Gabriel reports in the *Jahrbuch für Kinderheilkunde* that 428 scarlet fever patients were divided in two groups for the purpose of ascertaining the value of scarlet fever serum. One group was treated symptomatically, while the other received scarlet fever serum produced by the Behring works. Where no effect was apparent a second injection was performed after 24 hours. The results recorded were almost negative. The percentage incidence of complications in the injected series was 60·5, and in the controls 71; but if the complications due to the injections themselves are added (8·5 per cent.), the percentage complications in the injected series amounts to 69. Serotherapy was thus not very efficacious. Apparently the fever in the acute stage of the illness was reduced, but critical decrease of temperature was observed in a few cases only. Gabriel states that a definitive opinion cannot yet be given owing to the very benign character of the present epidemic.

Broadcasting and Medical Practice.

A somewhat curious judgment was lately given by a law-court in Karlsruhe. An engineer, being disturbed during listening-in by rattling in his wireless set, ascertained that this was due to high-frequency currents coming from diathermy and X ray apparatus of a neighbour who was a medical man. He therefore asked for an injunction, an action requiring that the latter should be prohibited from using this apparatus. Although it did not entirely agree with the plaintiff's demand, the court ordered the medical man not to use his apparatus between 12.30 and 2.30 P.M. or between 8 and 12 P.M., under penalty of an imprisonment not exceeding 6 months and a fine. This judgment has caused some astonishment in the profession. A medical journal asks whether the doctor should be prohibited, for instance, from using X rays at these hours to ascertain the presence of a foreign body—in order that the plaintiff may be able to hear operatic melodies or dance to the tunes of the broadcasting orchestra. The defendant has, of course, appealed to a higher court, requiring annulment of the judgment.

An American Hospital in Berlin.

Prof. Bucky, a radiologist formerly well-known in Berlin, has returned home after eight years' work in New York. He has been appointed radiologist at the Virchow Hospital in succession to the late Prof. Levy-Dorn, who was one of the earliest radiologists and died some time ago from X ray cancer. With the aid of the mayor of New York, of American financiers, and of the Rockefeller Fund, Dr. Bucky plans to establish an American hospital in Berlin, with an American staff and American nurses. The hospital is to be connected with a German-American medical society and will be a centre for American medical students and American medical men who come to Berlin for post-graduate study. Moreover, it is planned that young medical men on the staffs of Berlin and New York hospitals should be exchanged, so that they may become acquainted with the methods of treatment in the other countries.

Gonococcal Arthritis.

Dr. Müller reports in the *Archiv für Dermatologie* that of 10,570 patients with gonorrhœa 296 (2·8 per cent.) had arthritic complications, the percentage being in men 3·5 and in women 2·1. A connexion with trade or profession, season or time of incubation could not be ascertained, nor was trauma or over-exertion proved as a cause. In two-thirds of the cases the disease was monarticular. A certain predisposition to arthritis is shown, says Dr. Müller, by the fact that some patients are affected with arthritis whenever they catch gonorrhœa.

Premarital Advice.

The association of official matrimonial advisory boards has issued a warning against private institutions recently founded by philanthropic and benevolent societies. It explains that these institutions as a rule have not the necessary experience and that their work is thus apt to discredit activities of this kind and so hinder the development of the movement.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

X Ray Diagnosis of Early Phthisis.

AT the end of last year our premier public health journal called attention to the importance of the X ray film in making an early diagnosis of tuberculosis, and inquired if some progressive health department would not provide gratuitous X ray service for the benefit of people in the community unable to pay for it. This has brought out the information that the New York City Department of Health has already had such a service in operation for the past six months. The demand for this service has proved so great that a new station has recently been opened in Brooklyn, and two more are to be established shortly in New York. Patients are received only by reference from a physician to whom a written report is furnished. No treatment is offered to the patient, though the stations are prepared to help physicians to obtain suitable institutions whenever institutional treatment is indicated.

Mortality of Wage-earners in 1929.

With its usual promptitude the Metropolitan Life Insurance Company has brought out an analysis of the causes of death among the 19 million industrial policy-holders. In spite of the influenza epidemic new records for low mortality have been made in several respects. The tuberculosis death-rate of 85·6 per 100,000 is the lowest yet recorded, and leads to a prophecy that a rate in the region of 40 per 100,000 may be expected by 1940. The previous low point was 90·6 recorded in 1928. Low records have also been made for the communicable diseases of childhood, and for diarrhœa and enteritis. The present rate for the latter cause is 7·8, little more than one-quarter of the figure registered 18 years ago. The maternal mortality also showed encouraging improvement, declining to 13·5 per 100,000 from a previous low record of 14·2 in 1928. Organic heart disease and cancer continue to show rising mortality. The cancer problem is growing increasingly serious. In spite of its comparative accessibility and all the educational campaigns, cancer of the breast is responsible for a rising death-rate between the age of 45 and 64 years. There is no evidence of a significant decline in the cancer death-rate for any organ or part of the body. The 1929 death-rate for automobile accidents was 20·9 per 100,000, a rise of 12 per cent. over the previous year, and an increase of 809 per cent. over the rate for 1911. One-half of the automobile fatalities are pedestrian cases. From 35 to 40 per cent. are children under 15 years of age. The automobile is as dangerous to child life as measles, scarlet fever, and whooping-cough combined.

A slight increase is recorded in the rate for acute and chronic alcoholism. The present rate (3·4) is nearly six times as high as that for 1920, the first year of national prohibition. It is not quite so high as for pre-prohibition years, though if the deaths from wood alcohol and denatured alcohol be added and deaths in the United States are considered, the rate would equal or closely approximate those for certain pre-war years. The mortality from alcoholism among the 600,000 policy-holders in the Province of Quebec is much less than in the United States. If the rates for the latter had prevailed in Canada there would have been 288 deaths there in the last eight years instead of the 48 actually recorded.

Control of Narcotic Prescriptions.

Unusual powers are to be taken by the U.S. Commissioner of Prohibition if Bills now before Congress and actively supported by the Hearst Press should become law. The Commissioner will have free discretion to make regulations governing the issuing, suspension, and revocation of licences to prescribe narcotics. No one who has been convicted of any offence, however trivial, against a Federal or State law relating to narcotics may again be licensed under the provisions of this Bill. Nor may a narcotic addict be licensed, and it is left to the Commissioner to decide when a person qualifies for addiction. The Commissioner will decide what records must be kept, what drugs may or may not be used, what reports may be required from the licentiate, and so on. It is hardly surprising that the medical profession in this country does not welcome bureaucratic control of medicine by the State.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

Competitive Examination for the I.M.S.

IN the Leglislative Assembly on Jan. 28th a resolution was passed, in spite of official opposition, recommending that the Government should revive the competitive entrance examination for officers of the Indian Medical Service, the examination for this purpose to be held concurrently in England and India. The Government contended that the time for the revival of this examination had not yet been reached. The examination referred to has been in abeyance since 1915, candidates at present being selected after interview by a committee appointed for the purpose, and, at first sight, it might appear desirable that the method of selection by examination should be revived. This, at any rate, seems to be the opinion of Colonel Gidney, who, in supporting the motion as spokesman of the European group, said that I.M.S. officers recruited during the last few years were not up to the standard of those recruited before the war. But surely it is obvious that the alleged inferiority of present-day entrants is due, not to lack of a competitive examination, but to lack of competition to enter a service which has lost so much of its former attraction for recently qualified men. The mere revival of a competitive examination where there is little or no competition for entry is unlikely to improve the quality of the entrants. In former years one of the chief attractions of the I.M.S. was the chance of employment on the civil side, with the wide fields for clinical and research work which such employment offered. Now, after a number of years, during which extremely few Europeans could be spared for transfer to civilian duties from the military side, a diminution of military requirements, and the increasing numbers of British entrants recently recruited, will enable the way to civil employment to be opened up once more. It is to this fact, rather than to the revival of a competitive examination, that any future increase in the numbers and quality of I.M.S. entrants will be due.

Whatever political agitators may say, and in spite of the growth of medical education in India, that country will need British doctors for a long time to come. Even Mr. Gandhi (who was himself operated on by a British surgeon in the I.M.S.) would probably admit the truth of this statement. In any case, until there is a very considerable increase in the number of candidates a revival of the competitive entrance examination is unlikely to affect the standard of the entrants for the I.M.S.

Illicit Drugs.

Signs are not wanting that the smuggling of morphine and its derivatives, as well as of cocaine, is carried on to a large extent in India, and the customs authorities in the larger ports frequently find consignments of these drugs concealed in merchandise, or hidden away in the crew spaces, particularly of foreign steamers. For one case of this description which is discovered there must be many which pass undetected, and the profits resulting from traffic of this sort are so large that it is difficult to put a stop to it. There is reason to believe that considerable organisations are at the back of the trade, and a recent number of the *Pioneer* gives details of a case detected by the Cairo Narcotics Bureau which throws an interesting light on the methods employed. Suspicions having been aroused, a consignment of a thousand tins of powder glue from Basle was detained at the Cairo customs house. Every tin was opened, and four of them were found to contain a white powder which, on analysis, proved to be a derivative of heroin. The matter was followed up, and the Basle police unearthed an extensive organisation for the manufacture and distribution of illicit drugs possessing branches at Geneva, Lausanne, Zurich, Mulhouse, and certain German towns. Increased taxation of alcoholic liquors, and the stiffening-up of measures to check illicit distillation, are no doubt encouraging the consumption of narcotic drugs in general, and it is of the utmost importance that this underground traffic should be made as difficult as possible. If others of the wealthy interests involved can be run to earth a great advance will have been made.

Crimes of Violence.

The psychology of crime in eastern countries generally is perplexing. Has anyone explained, for instance, how it is that the peoples who profess that mildest of all religions, Buddhism—Chinese, Thibetans, Burmese—have evolved the most revolting tortures; or how it comes to pass that certain Indian communities, of orthodox Hindu principles and strictly vegetarian, are notorious for crimes of violence? Indian police records are full of cases which show how inflammable is the material with which the forces of law and order have to deal, and the following are a few which have recently been reported in the press, within a few days of each other. In one, a young woman who had acquired an intense dislike for her step-daughter, aged 8 years, took the child and placed it in an oven—subsequently removing it in order to torture it further with a sharp instrument. Here the motive was apparently revenge, owing to a beating she had suffered at the hands of her husband to whom the child had complained. In a second case, in which a light engine had collided with a motor-bus at a level crossing, killing four passengers and gravely injuring four others, the mob which collected, apparently incensed without reason, attacked the driver of the engine with stones and sticks, and attempted to force him into the furnace of his own locomotive. The man, in fact, was only saved by the plucky action of a railway policeman, who fought his way to him, and protected him until further assistance arrived. The origin of a third recent example was a feud which developed between two men and their elder brother on account of some money matters. The two younger brothers were on their way with 13 other men to another village when they were ambushed by the elder and some confederates, who attacked them and left no less than eight dead on the ground. The ferocity which produced the tragedy of Chauri Chaura, when every man of an isolated police post was murdered under circumstances of the utmost barbarity, is still not far to seek, and it is difficult to predict what developments the criminal mentality of the underworld may not evolve in India, where an old man has been known to offer himself to be butchered on his enemy's doorstep by his own relations, in order to enable a charge of murder to be fabricated against him; and where the penal code provides for the offence of cutting oneself, and shedding one's blood in a stranger's house in order to defile it, in retaliation for a refusal to give alms.

Shortage of Women.

It is remarkable that not only in towns and cities where an influx of males for industrial purposes may account for it, but also under other conditions, the female population of the Punjab, so far from exceeding the male, as in Great Britain, is actually considerably less numerous. The public health report for 1928, in drawing attention to the deficiency, comments on the fact that the rise in total population, which is occurring, is increasing rather than diminishing the relative shortage of women in the province. One factor in producing this disproportion is the excessive female death-rate; another is that the male birth-rate habitually exceeds the female. The director of public health is of the opinion that the most hopeful method of attacking this problem is by concentrating on measures to promote the welfare and improve the health of women, and he takes the opportunity of emphasising the desirability of renewed efforts in the field of maternity and child welfare work. It is noteworthy that in the year under report a considerable proportion of the excess in female mortality occurs between the ages of 1 and 5.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 22ND, 1930.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 376 (last week 322); scarlet fever, 2551; diphtheria, 1747; enteric fever, 31; pneumonia, 1624; puerperal fever, 46; puerperal pyrexia, 119; cerebro-spinal fever, 8; acute poliomyelitis, 4; acute polio-encephalitis, 1; encephalitis lethargica, 19; dysentery, 7; ophthalmia neonatorum, 102. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Feb. 25th–26th was as follows:—Small-pox, 621 under treatment, 18 under observation (last week, 563 and 30 respectively); scarlet fever, 2210; diphtheria, 2768; enteric fever, 16; measles, 1066; whooping-cough, 88; puerperal fever, 36 (plus 22 babies); encephalitis lethargica, 121; "other diseases," 17. At St. Margaret's Hospital there were 11 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (1) from enteric fever, 123 (48) from measles, 11 (2) from scarlet fever, 31 (2) from whooping-cough, 59 (15) from diphtheria, 46 (15) from diarrhœa and enteritis under two years, and 84 (12) from influenza. The figures in parentheses are those for London itself.

The fatal case of enteric fever outside London occurred in Preston. Fatal cases of measles were concentrated at Portsmouth and Manchester each 13, West Ham 9, Sheffield 6, Oldham 5. Bradford and Cardiff each reported 4 deaths from whooping-cough, Birmingham and Nottingham each 3. Diphtheria claimed 6 victims at Liverpool, 5 at Birmingham, and 3 each at Derby, Hull, and Merthyr Tydfil. There were 5 deaths from diarrhœa at Birmingham, not more than two in any other town. Deaths attributed to influenza were widely scattered, the highest figures being Manchester 6, Liverpool 5, Sheffield 4, and Cardiff 3.

The number of stillbirths notified during the week was 295 (corresponding to a rate of 44 per 1000 births), including 60 in London.

RATE AID FOR A HOSPITAL.—Tottenham District Council has decided to give the proceeds of a halfpenny-rate to the Prince of Wales's Hospital.

PSITTACOSIS.

To the Editor of THE LANCET.

SIR,—The recent observations of S. P. Bedson, G. T. Western, and S. Levy Simpson on the ætiology of psittacosis have rendered it doubtful if *B. psittacosis* (*B. aertrycke* (Mutton)) has anything to do with the present epidemic. In their series of cases it was impossible to find any bacteriological or serological evidence of this organism; on the other hand, their results suggest that the disease is due to a filtrable virus. In the paper on psittacosis by Dr. A. P. Thomson and Dr. W. T. Hillier in THE LANCET of Feb. 22nd mention is made of the agglutination reactions of some of the infected patients with organisms of the typhoid-paratyphoid group. In view of the negative findings in the cases reported by Bedson and others, it becomes a matter of considerable importance to estimate the true significance of these agglutination results. In this connexion I would recall some work by Dr. H. A. Fielden and myself, published in THE LANCET (1922, i., 1088). Large numbers of sera from members of the population who were not suffering from disease of an enteric nature were tested against *B. typhosus*, *B. paratyphosus* A, B, and C, *B. aertrycke* (Mutton), and *B. enteritidis* (Gaertner). The result of testing 1000 sera against these organisms was as follows:—

29	per cent. agglutinated	*B. typhosus*.
17	,, ,,	*B. paratyphosus* A.
23	,, ,,	*B. paratyphosus* B.
8	,, ,,	*B. paratyphosus* C.
16	,, ,,	*B. aertrycke* (Mutton).
11	,, ,,	*B. enteritidis* (Gaertner).

The macroscopic technique was employed and the agglutination occurred at titres of 1/20 or higher. The tests were performed a few years after the war, and therefore a considerable proportion of this agglutination was, no doubt, the result of preventive inoculation with TAB. vaccine. This became clear when the sexes were taken separately. Since many more men than women had received preventive inoculation, the percentage of males agglutinating was found to be much higher, thus:—

Percentage of 276 sera from males.	Percentage of 165 sera from females.	Organism agglutinated.
42	5	*B. typhosus*.
28	2	*B. paratyphosus* A.
39	7	*B.* ,, B.
11	3	*B.* ,, C.
23	15	*B. aertrycke* (Mutton).
11	5	*B. enteritidis* (Gaertner).

This point was further emphasised by testing sera from people who were known not to have been inoculated.

Percentage of 111 males known to be uninoculated.	Percentage of 61 females known to be uninoculated.	Organism agglutinated.
4·5	1·5	*B. typhosus*.
Nil.	Nil.	*B. paratyphosus* A.
4·5	4·9	*B.* ,, B.
4·3	5·6	*B.* ,, C.
9·9	10·9	*B. aertrycke* (Mutton).
3·6	7·8	*B. enteritidis* (Gaertner).

B. psittacosis is now regarded as being identical with *B. aertrycke* (Mutton), and therefore from the above evidence it is justifiable to expect about 10 per cent. of the uninoculated and approximately double this percentage of the inoculated population to agglutinate this organism. As regards the agglutinin titres which were encountered for *B. aertrycke* (Mutton), the majority were on the 1/20, 1/40, and 1/80 mark, but a titre of 1/320 was obtained in an uninoculated person who had never had enteric or gastro-enteritis, and a titre of 1/640 occurred in an inoculated case. As a result of the work, we came to the conclusion that if a diagnosis was to be made on a single test, not less than a titre of over 1/1000 should be considered suggestive of infection with this organism; a titre of over 1/2000 is very strongly suggestive of infection. As these conditions have not been fulfilled in the cases of psittacosis referred to, it seems very doubtful if the agglutination results recorded have much significance.

In the current issue of the *British Medical Journal* Dr. J. C. Hamilton describes a case of infection with *B. enteritidis* resembling psittacosis. The diagnosis in this case was made because on the 10th day of the illness the patient's serum agglutinated *B. enteritidis* at a dilution of 1/50, and on the 20th day the same bacillus was agglutinated at a dilution of 1/25. If our tables are studied it will be seen that anything from 3 to 11 per cent. of the population can be expected to agglutinate *B. enteritidis* at titres of 1/20 or higher. In the course of our examinations, two titres of 1/320 were recorded in apparently healthy people, so that a titre of 1/50 can by no means be considered diagnostic. Furthermore, the fact that the agglutinins on the 20th day of disease had not risen above 1/50 is, to my mind, evidence against the patient suffering from an infection with this organism, for in these enteric infections the agglutinins usually increase rapidly and reach a maximum between the 18th and 21st days of disease. To give an example of this Dr. G. Selby Wilson and myself recorded a case of enteric infection due to *B. enteritidis* (THE LANCET, 1921, i., 16), and in this case the titre for *B. enteritidis* was 1/160 on the 12th day of disease, 1/320 on the 16th day, 1/3200 on the 22nd day; it then started to fall, so that by the 27th day it was 1/2000 and three weeks later it only reached 1/160.

For these reasons I do not consider that the serological results in Dr. J. C. Hamilton's case warrant a diagnosis of infection with *B. enteritidis*.

I am, Sir, yours faithfully,

ARTHUR B. ROSHER.

Charing Cross Hospital Institute of Pathology, W.C.,
March 3rd, 1930.

To the Editor of THE LANCET.

SIR,—Psittacosis is at present in the minds alike of doctors and the lay public, and at the risk of producing a redundance of clinical evidence I would ask space to report briefly a case at present under my care which presents some unusual features.

On Jan. 16th, 1930, Mrs. B. was given a blue front Amazon parrot. Very soon it exhibited signs of ill-health and died on Jan. 28th, 1930. The autopsy revealed "parrot disease." On Jan. 29th, 1930, Mrs. B. complained of sore-throat and headache, and sent for Dr. Arnold Morris. After two or three days in bed her condition showed improvement, but by the end of the first week of her illness she settled down into a typhoid state; twitchings and delirium occurred together with sleeplessness and severe occipital headache. In this condition she was admitted to the Warneford Hospital on Feb. 5th, 1930. She was profoundly ill. T. 105° F., P. 140, R. 30. At this stage the only positive physical signs were a little impairment and a few crepitations in the left axilla; there were no signs of pneumonia. Respirations were calm, pulse-rate rather frequent. The spleen was just palpable. The patient remained in a drowsy state and on the tenth day of the disease signs of consolidation occurred at the bases of both lungs. At the same time a crop of rose spots appeared over the lower part of the chest and on the next day there were several more on the back. On the twelfth day the temperature began to fall and had reached normal by the fifteenth day, the pulse-rate gradually subsiding but still remaining rather more frequent than is usual in this infection.

The Widal reaction on the tenth day showed a partial reaction 1–15 to *B. typhosus*, otherwise no reaction with the enteric group nor with *B. psittacosis* (two strains). On the seventeenth day all these reactions were completely negative. The blood picture showed a leucocyte count of 7200 per c.mm., of which 83 per cent. were polymorphonuclear and 17 per cent. were lymphocytes. Culture of fæces and urine showed no evidence of pathogenic bacilli of the enteric group. The recovery of the patient is now apparently complete.

The chief points of interest of this case seem to be: (1) The certainty of the diagnosis from the circumstances of the case and the clinical features. (2) The complete absence of any cough or sputum. (3) The occurrence of rose spots. (4) Negative serological and bacterial findings.

Whether the "filtrable virus" described by Bedson, Western, and Levy Simpson is capable of producing in man a condition so similar to that caused by the typhoid group of organisms must at present remain sub judice.

I am, Sir, yours faithfully,

Leamington, Feb. 28th, 1930. FRANK CLAYTON.

THE MECHANISM OF PULMONARY COLLAPSE.

To the Editor of THE LANCET.

SIR,—In massive collapse of the lungs Sir John Rose Bradford selected a very appropriate subject for his lecture to the Royal College of Surgeons. Few subjects that are of equal interest to both physicians and surgeons are more frequently overlooked, and none has given rise to greater diversity of opinion among those who are familiar with it.

Sir John Rose Bradford's work is well known to all those who take an interest in massive collapse, and the profound theory, which he has formulated as a result of his study of the phenomenon in its most baffling form, following injuries of the chest wall, has influenced many in their opinion of the probable mechanism of its causation. As one, however, who has not had, and probably never will have, an opportunity of studying massive collapse in these very unusual circumstances, I may perhaps be excused for pleading that there is another way of approaching the problem, that is by endeavouring to explain these apparently inexplicable cases in the light of what emerges as tolerably certain from a study of massive collapse in its less complicated forms.

It can be safely said that there is only one method of producing massive collapse experimentally, and that is by complete obstruction of the bronchial tree. So long ago as 1845 it was known that obstruction of a bronchus was invariably followed by collapse of the area of lung which it supplied, providing that its blood-supply was intact; and since then this finding has withstood the brunt of repeated investigations.

It is equally certain that the sum of the experimental attempts to produce massive collapse in any other way—such as by completely or partially paralysing the respiratory musculature, or by the application of all varieties of stimuli in the hope of awakening a hidden reflex—is complete failure. If we add to these considerations the evidence of the physical signs of massive collapse (which, I hope Sir John Rose Bradford will agree, can be admirably explained in their earliest phase by the presence of a bronchial block, and later, by the persistence of secondary changes of all grades of severity in the lung, when the obstruction has been removed), it appears likely that the elucidation of the mystery of massive collapse will be best served in the future if we ask ourselves, how can bronchial obstruction have come about in this case, and why?

It is possible, for instance, that Pasteur's post-diphtheritic cases were due to the direct spread or aspiration of the membrane rather than to diaphragmatic paralysis, which was not present in all the cases, and it is probable that those cases occurring in association with high transverse lesions of the spinal cord, anterior poliomyelitis, debility, &c., owe their bronchial obstruction to the same factors which appear to predispose to the post-operative cases—namely, bronchitis, postural deflation of the lungs, inhibition of the cough reflex or suppression of the expulsive efforts; and gravity. Even the most difficult cases of all—namely, Sir John Rose Bradford's contralateral cases following slight injuries—may admit of the same explanation; because the lungs in the thorax have been found to respond to non-penetrating trauma in much the same way as the brain in the cranium, and to sustain the greatest damage sometimes by a contre-coup mechanism on the opposite side to the injury. Given this contralateral damage, with voluntary suppression of the cough reflex for the short period which is necessary for it to pass into abeyance, and one has the material for an explanation of the occurrence of contralateral massive collapse, which is compatible at once with the physical signs and with the experimental evidence, which, if it is to be regarded as untrustworthy, is certainly unanimous.

I would like, Sir, to add a few observations on Dr. Fuller's interesting investigation into post-operative pulmonary complications at University College Hospital (THE LANCET, Jan. 18th, p. 121). Although it is a little difficult to arrive at figures which are strictly comparable, it does not seem that the incidence of complications encountered by him is any larger than that observed by Dr. Sheret and myself (THE LANCET, 1928, ii., 111), which at the time seemed appallingly large. Indeed, considering that the series in both papers is comparatively small (Dr. Fuller's is much larger than our own), one is surprised at the very striking similarity between the findings. Cases presenting Pasteur's classical picture of massive collapse, and cases of undoubted embolic origin, were few in both series, and of about equal frequency. We have also encountered, then and since, a complication distinguished from the others by the persistent gravity of the patient's condition and physical signs, suggesting lobar pneumonia from the onset. There, however, the resemblance to lobar pneumonia ended. The patients all succumbed between the fifth and ninth day after operation, with no other cause for death than the lung condition, and at autopsy a diffuse pneumonitis was found with more or less confluent gangrene. These cases probably constitute a distinct group, but it is questionable whether true lobar pneumonia occurs among the complications of operations.

The difference between our conclusions concerns the remaining, and, incidentally, the great bulk of all the cases, which Dr. Fuller regards as primary broncho-pneumonias, and in which we prefer suspect cases of massive collapse and its sequelæ. The question is, of course, quite an open one. Bronchitis, which is undoubtedly the most frequent of all post-operative chest complications, will predispose to either, and in many instances the lung changes are patchy and do not involve a whole lobe. But our main point remains, that if all cases of massive collapse are to be recognised, cardiac displacement, which can be demonstrated clinically, must not be regarded as a sine qua non for the diagnosis for the following reasons:—

1. Because, in a great many instances, it is impossible to form even an approximate idea of the position of the heart.

2. Because bilateral collapse of the lower lobes undoubtedly occurs, the heart necessarily remaining normal in position, while in those cases following severe upper abdominal operations, in which a marked degree of postural deflation has occurred, one lower lobe can, in our opinion, completely collapse without leading to any cardiac or mediastinal displacement, the upper lobe being able to fill the diminished pleural space; and in cases in which the left lower lobe alone is involved, we think that the heart follows the receding lung, not so much by a lateral movement, as occurs on the right side, as by rotating backwards—a displacement which cannot be appreciated clinically.

3. Because, in a great many of these cases, early X ray examination will reveal displacement of the heart or mediastinum, or both, the existence of which is not suspected, as well as showing a marked diminution in the size of the shadow cast by the affected lower lobe.

Further, we think that the symptomatology, physical signs, and clinical course of the cases in this group are so similar to those of the cases in which cardiac displacement is demonstrable clinically, that it is impossible to escape the inference that in their essentials there is no difference between them.

Our experience of the effects of postural drainage of the bronchial tree leads me to disagree with Dr. Fuller's opinion that the first day temperature is not to be attributed to the chest changes, because patients so drained rarely have any temperature at all; and while it is quite true to say that the "collapse," produced by artificial pneumothorax, is not followed by inflammatory complications, the lung in these cases is not completely airless, and the evidence, both experimental and clinical, is very definite that the airless lung behind an occluded bronchus cannot remain undamaged for more than 72 hours, and rarely as long as that.

Although post-operative postural drainage of the bronchi is not comfortable for the patient, is unorthodox, limited in its applicability, and even, I suppose, not entirely free from the objection that it may expose the patient to greater dangers that it is designed to prevent, it certainly produces a greater reduction in the incidence of chest complications than has been claimed for any other method.

I am, Sir, yours faithfully,

London, Feb. 24th, 1930. CHARLES R. BOLAND.

THE APPLICATION OF GAMMA RADIATION TO DEEP-SEATED TUMOURS.

To the Editor of THE LANCET.

SIR,—In the application of gamma radiation to deep-seated tumours two or more convergent beams so adjusted as to intersect within the tumour have been used. I suggest, in what follows, a mode of application which appears to possess certain advantages and which, so far as I know, has not hitherto been tried.

One beam only is required, but this beam is caused to describe continually a conical path, the apex of the cone being within the tumour. Thus the radiations reaching the tumour are virtually focused in the tumour, in the sense that this becomes the region of maximum radiation. As the beam sweeps out its conical path its track where it traverses the surface of the body approximates to a circle of entry. The beam traverses this circle in one revolution. It follows that the risk of surface burns must be much less than if a fixed beam, or two or more such fixed beams are employed. This reasoning applies also to risk of lesions within the body of the patient. In fact the concentration is obviously a maximum within the tumour and falls off rapidly in the surrounding tissues. The fact of continually changing inclination of the rays within the tumour might be expected to be in itself advantageous. Of course, the use of two or more such beams suitably spaced around the cone of revolution would be admissible.

A very simple mechanical arrangement will suffice to realise this mode of application of gamma radiation. The drive may be purely mechanical or electrical, and the whole apparatus carried on a suitable stand, combining steadiness with easy adjustment of the cone of radiation.

It will be evident that the convergent rotating beam may be caused to describe any path called for by the extent and form of the tumour. A central rotating cam of the required form and dimensions would suffice for this purpose.

I am, Sir, yours faithfully,
J. JOLY.

Radium Institute, Royal Dublin Society, March 4th, 1930.

FOOD OR DRUG?

To the Editor of THE LANCET.

SIR,—In your annotation (March 1st, p. 475) you say I omit "to point out that the four doctors in question have had all the consideration which the Insurance Acts allow." In my letter to the *Saturday Review* to which you refer I did no more than call attention to a report in the *British Medical Journal* and draw certain fairly obvious deductions. I cannot believe that you can have any real sympathy with a procedure which, while holding up for our admiration the general professional conduct of the four men concerned, condemns them to an extremely heavy fine. Do not lose sight of the fact that, according to the report, they had the sympathy and support of the Ministry of Health; that it was the London Panel Committee, not the Ministry, which condemned them.

There is now a fresh, most perplexing, point. In the current *New Statesman* is an account of what is said actually to have happened. If that be a correct account the whole affair appears queer indeed; for it is there stated that when "examined first by a professional committee of their colleagues" that committee expressed the opinion "that the prescribing was not in excess of what was reasonably necessary for the adequate treatment of the insured patients."

I submit that the profession as a whole should see the entire facts published in the responsible medical journals. The matter by now has gone far beyond any hair splitting as to whether "malt with oil" is a food or a drug. That, together with the exact definition of liver extract, insulin, pituitrin, &c.—all used to make up deficiencies—is a nice debating point. The question at issue is one concerning the administration of justice within the profession. As such, *all* the facts should be published.

I am, Sir, yours faithfully,
Walsall, March 2nd, 1930. FRANK G. LAYTON.

To the Editor of THE LANCET.

SIR,—In your issue of March 1st you refer editorially to the penalising of four practitioners to the tune of £100 for the offence of prescribing for their panel patients drugs and appliances more frequently than is customary in their area; and you raise an objection to Dr. Layton's criticism of the Insurance Committee's action, on the ground that he omitted "to point out that the doctors in question had all the consideration which the Insurance Acts allow." It is interesting to recall that an almost identical comment was made on the trial and sentence of Jeanne d'Arc. However, it is not to protest against complacency that I am writing, but to ask you to correct, or to allow me to correct, two or three misstatements of fact. You say that "their case was examined by a professional committee of their colleagues and then by the Insurance Committee, with a final appeal to three independent referees. This board of referees was composed of two medical practitioners and one lawyer, in actual practice. Each time the doctors had the opportunity of stating their position." I write as one of the four practitioners to whom you refer, and my knowledge is at least first-hand. As reported in the *British Medical Journal*, the charge against us of excessive prescribing was heard by a special Subcommittee of the London Panel Committee deputed for that purpose. Twelve members were present. An entire afternoon was devoted to this case, and to this case alone. The "charge against us" was presented at great length by a representative of the Ministry of Health. After hearing explanations by the senior partner of the firm, this Committee reported that it "was of opinion that the prescribing was not in excess of what was reasonably necessary for the adequate treatment of the insured patients." The Panel Committee (which had not heard the evidence) declined to accept this verdict, and referred the matter to a Committee with a different personnel, six members of which never heard the evidence on either side. This semi-absentee Committee reversed the verdict of the body which had heard the evidence, and its report was accepted by the Panel Committee, before which the practitioners concerned were at no time given an opportunity of appearing. They requested to be allowed to make representations to the Insurance Committee, but were given no chance of doing so. The tribunal of "three independent referees" to which you refer had not the composition you state. They were appointed and paid by the Ministry of Health, one of the parties to the dispute. "A lawyer in actual practice" was not one of them.

Your statement that the doctors "prescribed cod-liver oil for its nutritive value" is not correct. The practitioners were definite on this point, and their statement was undisputed. Throughout, the whole discussion on this matter was as to the anti-infective value of vitamin A and the justifiability of prescribing preparations containing it.

So much for misstatements. Your leader-writer omits to mention a number of relevant facts. He makes no reference, for example, to the fact that, although these practitioners issued a greater number of prescriptions than the average for London, their attendances on their patients were also approximately double the average. He gives no hint of the tribunal's finding that the practitioners concerned had "organised a highly efficient treatment centre in a poverty-stricken quarter, where the chances of health are poor indeed." Nor does he refer to the recommendation that, if any penalty were thought necessary, it should not be a "punitive" one. You will, I am sure, agree that any criticism has more value if the facts are all on the table.

I am, Sir, yours faithfully,
March 2nd, 1930. ONE OF THE FOUR OFFENDERS.

CENTRAL CLINICS FOR RHEUMATISM.

To the Editor of THE LANCET.

SIR,—In the leading article on Central Clinics for Rheumatism in your issue of March 1st, 1930, in speaking of the new clinic for the treatment of rheumatism, to be erected by the Bermondsey Borough Council, you make the following statement:—

> "In the first place, the London County Council declined to advance a loan on the ground that, under the new Local Government Act, the County Council itself was the proper authority to provide treatment of this kind."

I feel it necessary to point out to you that this statement is misleading and contrary to the facts. The original proposal put forward to the Council by the Bermondsey Borough Council was for the erection of a clinic:—

(1) for the diagnosis and treatment of cancer, rheumatoid arthritis, rheumatism, &c.; and

(2) to replace the existing tuberculosis dispensary and the maternity and child welfare clinic in Grange-road.

The Council declined to sanction the loan asked for by the Borough Council for these purposes on the grounds: (1) That cancer was a disease which could not be adequately dealt with by means of an ad hoc clinic, but required facilities for its diagnosis and treatment which could only be provided in a properly equipped hospital. (2) That the existing tuberculosis dispensary in Grange-road was suitable and adequate for its purpose. (3) Furthermore, it was pointed out that cancer, &c., might cover the whole range of medicine and surgery. The Borough Council appealed to the Minister of Health, who directed that a public inquiry should be held by one of the medical inspectors of the Ministry. Following upon the report of the inspector, the Minister directed the Borough Council to make a new application to the Council limited to rheumatism and the provision of more suitable premises for the tuberculosis and maternity and child welfare work of the Borough Council.

I am, Sir, yours faithfully,
F. N. K. MENZIES.

L.C.C. Public Health Department, County Hall, S.E.,
March 4th, 1930.

To the Editor of THE LANCET.

SIR,—In commenting on the Peto Place Clinic for Rheumatism in THE LANCET of last week (p. 480) you say that "the costs of construction and equipment have been covered by the interest on the appeal fund and the capital remains intact." The whole of the sum raised for the construction and equipment of the Clinic has been expended. The interest earned on donations as they were received by the British Red Cross Society from the public more than met the cost of making the appeal.—I am, Sir, yours faithfully,

F. C. DAVIES,
Secretary, Central Clinic for Rheumatism.
19, Berkeley-street, W., Feb. 28th, 1930.

WE have received from Mr. Haydn Brown in reference to a review last week of Dr. Edmund Jacobson's book, "A Physiological and Clinical Investigation of Muscular States and their Significance in Psychology and Medical Practice," a letter in which the writer finds clear indications that Dr. Jacobson has reached essentially the same conclusions and practical results as were published by him in 1918 in "Advanced Suggestion." He concluded by hoping that his name may soon be restored to the Register "upon my again expressing regret that I should ever have felt compelled into occasions which have offended them."

Obituary.

MAURICE R. J. HAYES, F.R.C.S. IREL.

DR. HAYES.

Photograph by Lafayette.

Prof. Maurice Hayes, who died on March 2nd, was born in County Limerick 51 years ago, and was educated first at Limerick, and later at the Catholic University School of Medicine, Dublin. Qualifying in 1906 he became a Fellow of the Royal College of Surgeons in Ireland in 1908. For a short time he was engaged in general practice in Dublin, but having been appointed to the charge of the X Ray Department of the Mater Misericordiæ Hospital, he determined to specialise in radiology. This decision was fully justified by results, for in a brief time he was in the enjoyment of a large practice in that field, and was regarded as the leading radiologist in Ireland. During the war he was attached to the staff of the Dublin Castle Red Cross Hospital, and in 1917 he served in the British Expeditionary Force in the "83 (Dublin) General Hospital." In 1921 he was appointed to succeed the late Dr. Martin Dempsey as professor of materia medica and therapeutics in University College, Dublin, National University of Ireland. Shortly after this, pressure of work necessitated his retirement from the staff of the Mater Misericordiæ Hospital, for his private practice was largely increasing. In the summer of 1922 a new and urgent duty was cast upon him. When hostilities broke out in Ireland between the Provisional Government and the Republicans Maurice Hayes was invited by the Government to organise an army medical service. He was appointed Director-General, with the rank of Major-General, and was so successful in his task that he was able to hand over a well-organised and equipped medical service to his successor after a tenure of office of only nine months. Hayes was a frequent contributor to the Royal Academy of Medicine in Ireland in subjects connected with X rays and radium, and many of his papers have appeared in the special journals.

In his younger days Hayes did notable work for the profession. When the National Health Insurance Act was introduced nearly 20 years ago he was appointed honorary secretary of the Dublin Medical Committees and later became secretary of the Irish Medical Committee. As such it fell to his lot not only to do the main work of organising the medical profession in Ireland, but also to conduct the protracted negotiations which finally led to a satisfactory settlement of the difficult problem of certification. The work which he did in this respect was not forgotten in Ireland, and when the Irish Free State Medical Registration Council was established in 1927, he was induced to go forward as a candidate for one of the positions as representative of the profession on the Council, and had no difficulty in heading the poll. His death will necessitate an election to fill the vacancy.

It will be seen that Dr. Hayes had a busy and active professional life. His work as a radiologist together with his duties as a university professor would have been enough for most men, and too much for many. But his sense of duty seldom allowed him to avoid or refuse a responsibility.

A personal friend of many years' standing writes: "In Maurice Hayes we have lost one of the most great-hearted and generous men I have known. He was full of ambition for the advance of knowledge and for the credit of Irish medicine, but of personal ambition he had not a trace. The most modest and retiring of men, loving privacy and hating publicity, it fell to his lot to fill more than one position of importance to his profession or to his country. With an unusually sensitive conscience in regard to himself he never looked for faults in others. One of the most devout of men in his personal life, differences of religion or politics meant nothing to him where judgment of men or where friendship was concerned. Generous in thought he was also generous in deed. His life and influences made many a man a better man. His death leaves many lonely."

MEMORIAL TO A MEDICAL MAN.—A cot in the children's ward of the Taunton and Somerset Hospital is to be named in commemoration of the late Dr. J. A. Macdonald, who was honorary physician.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

THE MENTAL TREATMENT BILL.

THE Mental Treatment Bill was further considered by Standing Committee A of the House of Commons on Thursday, Feb. 27th. Mr. CECIL WILSON was in the chair.

Power to Receive Voluntary Boarders.

On Clause 1, Lieut.-Colonel FREMANTLE moved in subsection (1) after the word "home" to insert the words "or training or other establishment," but withdrew and accepted the Minister of Health's suggestion that the words "or place" should be inserted after the word "home."

Mr. KINLEY moved in Subsection (1) to leave out the words "Board of Control," and to insert instead the words "Minister of Health." He said that as the Bill stood, voluntary patients were to be asked to go to an institution under the control of the Lunacy Commissioners. Their own doctor had no control, and the local authority and the Minister of Health had no control. That, he suggested, was the very opposite of what was intended.

A Destructive Amendment.

Mr. GREENWOOD said that this was an amendment of the most far-reaching importance, and its acceptance would mean the destruction of the Bill. Such patients as those mentioned by Mr. Kinley need not go to a lunatic asylum; they might go into a hospital or a nursing home approved for this purpose. While it was true that the Board of Control could go to one of these institutions and certify a person, it was also true that they could go there and see that a person was discharged if he was being improperly detained. As a matter of fact, the visit of the Board of Control was designed as one of the checks and one of the forms of protection for individuals who entered such an institution. The Royal Commission considered whether it was possible in practice to differentiate lunacy administration as a whole from the aspect of mental treatment with which they were concerned in this Bill, and considered that it would be unscientific to treat the different manifestations of mental illness under two distinct systems. The report went on to elaborate the case against attempting any clear-cut differentiation between the two methods of treatment. There appeared to be an assumption that this was the first time that the Board of Control had ever had anything to do with voluntary boarders, but such was not the fact. What this Bill did was to extend to public institutions a form of treatment which hitherto had been practically confined to certain private institutions; and if they looked at the figures they would see that the Board of Control to-day was in very large measure dealing with voluntary boarders who were not certified. During 1929 there were admitted to registered hospitals 562 certified patients and 668 voluntary patients.

Dr. VERNON DAVIES: Do those figures include Scotland?

Mr. GREENWOOD said that he was informed that they did not; and therefore his case was strengthened. During 1928, 974 certified patients were admitted to licensed houses, and 757 voluntary boarders, which meant that in those institutions to-day nearly half the people were not certified and were actually under the control of the Board. One had also to remember that these patients were not permanently in one category. If this Bill passed there would be three categories. First of all there would be the voluntary boarder; secondly, the person who had lost volition for the time being, but was not to be certified; and, thirdly, the persons who were certified as being of unsound mind. A person might pass from one of these stages to another, and obviously it was not possible administratively to change over from the Board of Control to the Ministry of Health when a man fell out of one category into another. They were not in this Bill dealing with substantial reforms of the principal Lunacy Act; they were trying to make special provision for people who had only been provided for in the past at the cost of certification, and incurring the pauper stigma. If the Committee insisted on substituting the Minister of Health for the Board of Control in this case, it would mean a complete overhaul of the principal Act, which was obviously impossible in this measure.

Prevention of Mental Illness.

Dr. DAVIES said that they all recognised that the Board of Control at present had a large number of voluntary boarders under its care, but he suggested that this Bill was going to change the whole outlook on this question. They were out for the prevention of mental illness rather than its treatment. Once the Board of Control came in, the association with lunacy would immediately be brought to the patient's mind, and the mind of his friends, and they would ask themselves whether the case was a border-line case, and whether the doctors out of kindness of heart were trying to avoid the stigma of lunacy being attached to the patient. One of the terrible problems of the present day was the large number of suicides. The total number of suicides in Great Britain in 1913 was 3791. In 1917 and 1918 the figures curiously enough came down to 2700 and 2600 respectively; but in 1919 and 1920 the figures were 3500 and 3600 respectively. From 1921 to 1928 the figures increased from 4000 to 4800. There was an increase for every year except one during that period. In 1927 the figure was 5100, and in 1928, 5356. He quoted a letter from Dr. G. M. Robertson to the *Times* as showing that it was the stigma of certification that had prevented certain cases on the border-line from submitting themselves to the present methods of treatment under voluntary control, and they had therefore become suicides. It was the fatal flaw of this Bill that these people were deterred from seeking early treatment because of their fear of inspection by the Board of Control. He was convinced that the intervention of the Board for these voluntary patients would wreck this part of the Bill.

Sir BOYD MERRIMAN thought that it was possible that there might be in certain cases abuse of any form of voluntary treatment, and it was absolutely necessary that there should be some form of control at every stage. It would be a profound mistake to take away the control of the Board in regard to these voluntary patients.

Mr. C. WILLIAMS opposed the amendment.

Mr. GOULD said he hoped the Minister would accept the amendment. They desired in this Bill to get a new health service treating these lighter cases of mental illness with a new psychology.

Provision for Voluntary Rate-aided Patients.

Miss SUSAN LAWRENCE (Parliamentary Secretary to the Ministry of Health) said that people with money who felt that their mind was going could go to a doctor as a voluntary patient under Section 229 of the Lunacy Act. They could go to a licensed house with the consent in writing of two of the Commissioners, which meant the Board of Control. What they were doing now was to extend to voluntary rate-aided patients almost exactly the same provisions as had been built up for those who could afford to pay. The Maudsley Hospital and another established under special Acts by the London County Council received lunatics. The Maudsley Hospital was under the Board of Control. Patients came in voluntarily, and she regretted to say that some of them passed into another stage and were certified. There was no reluctance to enter the Maudsley Hospital or the other registered hospital. The difficulty was to find accommodation for patients who wished to enter. This was a pure bogy; it was absurd to talk of separating the early mental cases from severe mental cases.

Dr. DAVIES: You do not put them together.

Miss LAWRENCE said that she meant that they needed the same doctors and staff. If these early cases were put in a special asylum they would not get good expert specialist service.

Mr. RHYS DAVIES said that the speech of Miss Lawrence had convinced him that the Bill was not the measure he thought it was to be. He never thought for a moment that the Board of Control was going to get greater control over these people than ever before. The Bill definitely put the voluntary boarder for all practical purposes in the same category as the certified lunatic.

Dr. MORRIS-JONES said that the Bill on second reading received universal assent, and passed without a division, but there were amendments on the Order Paper which were fundamentally opposed to the principle of the measure. If they were carried they would jeopardise the Bill.

Dr. HASTINGS said his own view was that people who were suffering from mental disease ought to be under the supervision of the Board of Control. Obviously they were the people who had experience in dealing with them, and they were also the people who would be able to see that the institutions were carrying out their duties in an efficient way. But another question had been introduced—namely, whether the hospitals or institutions in which the early cases were treated were in a definite connexion with lunatic asylums. That was a very doubtful point indeed, and he would be rather slow in accepting it. It was much better to have these people under the supervision of the Board of Control.

The amendment was negatived.

Other Amendments.

On the motion of Mr. GREENWOOD, an amendment was agreed to leaving out in Subsection (1) the words "with the consent of the Board into single care," and inserting instead the words :—

> " into the charge as a single patient of a person so approved, and any approval under this section may be granted subject to such conditions as the Board think proper and may be revoked at any time."

Subsection (2) of Clause 1 provides that parents or guardians may apply for persons under 16 to be received as voluntary patients.

Mr. Womersley moved an amendment substituting the age of 18 for 16. He said that the amendment was put down on behalf of the *Municipal Corporations Association.*

Mr. Greenwood said that in the original Bill the age was 18, but after a very full discussion in the House of Lords, it was decided to adopt the age of 16, that being the age at which a person could legally marry. Although he would have preferred 18, he did not think that it would serve any good purpose to re-open the whole question with the subsequent delays that would ensue.

The amendment was rejected by 33 votes to 4.

Mr. Greenwood moved an amendment to Subsection (2) providing that the written application should be made " to the person in charge."

The amendment was agreed to.

A further amendment moved by Mr. Greenwood, substituting the word " patient " for " boarder " was also agreed to.

Captain Gunston moved in Subsection (3) to leave out the word " person " (" a person who has been approved,") and to insert the words " medical practitioner." He said that he did this for the sake of clarity.

Mr. Greenwood said that it was clearly intended that the person should be the medical practitioner. but in order to remove any doubts he would accept the amendment.

The amendment was agreed to.

Lieut.-Colonel Fremantle moved an amendment to provide that the recommendation would have to be both by the Board of Control and by the local authority. He said he proposed this particularly at the instance of the Council of Mental Hygiene. The medical superintendents in their association would prefer that the local authority should not be given the power. It stood to reason that there might be some doubt whether the local authority would always in a personal consideration like this be absolutely wise in their decision. Therefore it was felt that the Board of Control should have a share in the appointment.

Mr. Greenwood said that he really could not accept this amendment. The authorities concerned were the responsible local authorities—the county councils and the county borough councils. He dare not ask them to submit to this ; they would be up in arms.

Lieut.-Colonel Fremantle said after the explanation of the Minister, although he did not agree with him, he would withdraw his amendment.

The amendment was withdrawn.

Sir Boyd Merriman moved in Subsection (5) to leave out the words :—

> " If any voluntary boarder by or in respect of whom such a notice has been given is not allowed to leave the institution, hospital, home or place at the expiration of the notice, he shall be entitled to recover as liquidated damages from the person in charge ten pounds for each day or part of a day during which he is detained."

He said that these were the words that settled the sum at £10 a day as liquidated damages for a voluntary patient who was retained after the 72 hours notice of desire to leave. He urged that the amount of the damages should be left to the court of law to which the patient would in any case have to go.

Mr. Greenwood said that he was inclined to think that £10 was an unnecessary limit in the case of wrongful detention. He would therefore accept the amendment, which was carried by 21 votes to 13.

The Committee adjourned.

The Mental Treatment Bill was further considered by Standing Committee A of the House of Commons, on Tuesday, March 4th. Mr. Scurr was in the chair.

Safeguarding the Proprietor of a Mental Institution.

Mr. C. Williams moved an amendment on behalf of Mr. Womersley, to the effect than any person received as a voluntary boarder should leave the institution, hospital, home, or place, upon receiving from the person in charge 72 hours' notice in writing requiring him to leave, or, if he was a person under the age of 18, upon such notice being given to his parent or guardian.

Mr. Greenwood (Minister of Health) said that the words of the amendment added nothing to the Bill, but they might lead to difficulty by relieving the owner of a private institution from liability for damages for breaking a previous agreement made with the patient or his relatives, if he had given 72 hours' notice.

Dr. Vernon Davies said that he thought they ought to put something in the Bill to safeguard the proprietor of a mental institution against a person who was not quite suitable for his establishment, and who refused to leave when requested to do so.

Dr. Morris-Jones said he thought there was something in the amendment. It was possible that they might get very obstreperous patients in these institutions, and the proprietor ought to be allowed to give such patients notice of discharge.

Miss Susan Lawrence (Parliamentary Secretary to the Ministry of Health) said that the persons who conducted these private mental institutions were men of considerable experience. They had the right to make any sort of conditions they pleased before they took anyone into their house. It was not a sensible thing to take out one condition in such an agreement, and put it into an Act of Parliament. Medical men of all people should be most chary of interfering with private arrangements between the patient and his doctor.

Mr. C. Williams suggested that the matter might be reconsidered before the Report stage.

The amendment was negatived.

Lieut.-Colonel Fremantle moved a further amendment to the effect that the person in charge should have power to admit or to discharge a voluntary patient, and to take steps to have such patient dealt with under the principal Act, or under Section 5 of this Act, with the approval of the Board of Control. He said that although this included the point dealt with on the previous amendment, it also dealt with an entirely different point. He had been asked to put forward this amendment by the Medical Psychological Association, representing the superintendents, the Medical Women's Federation, and the Council for Mental Hygiene. The object was to give a definite status to the person in charge.

Mr. Greenwood said that he could not accept the amendment which he thought was a piece of sheer bureaucracy. It meant that the person in charge was to be at liberty, if he so wished, to act quite irrespective and independently of any arrangements that might have been made by the authority responsible for the institution. He could not conceive that the local authorities would be in favour of this amendment.

Dr. Davies, in supporting the amendment, said that a patient in an institution might show himself to be undesirable morally, and the person in charge ought to be enabled to deal with such a case.

The amendment was rejected by 27 votes to 3.

A Strengthened Clause.

On the question that Clause 1 as amended should stand as part of the Bill.

Mr. C. Williams asked if the medical members of the Committee were satisfied that the position of the patients was now sufficiently safeguarded.

Dr. Vernon Davies replied that, speaking as a medical man, he thought the amendments inserted had definitely strengthened and improved the Clause. Although the Clause, perhaps, did not go as far as one would wish, there was every reason to congratulate the Committee on the changes which had been made.

Sir Boyd Merriman also expressed the view that the Clause had been improved by the insertion of the amendments.

The Clause was then added to the Bill.

Notice of Reception.

Clause 2 provides for notice of the reception, death, or departure of voluntary boarders, and for boarders who become incapable of volition.

Dr. Vernon Davies moved the omission of Subsection (1), which provides that where a person is received as a voluntary boarder, notice of his reception shall, before the expiration of the day next following the day on which he is received, be sent to the Board of Control by the person in charge. He said that the obligation to give notice to the Board of Control would prevent voluntary patients from submitting themselves for early treatment as the association of the Board of Control with lunacy was a very strong factor in the minds of these people. They might be wrong, but the idea was there, and it had to be reckoned with. He wished to delete the Subsection in order to encourage voluntary patients to go in at the earliest possible moment with the knowledge that they would in no sense be under the supervision, knowledge, or control of the Lunacy Commissioners.

Mr. Greenwood opposed the amendment. He said that a long discussion took place on the Board of Control last week, and the Committee could not re-open the matter. The Subsection was an essential safeguard to the liberty of the individual, and must remain as an integral part of the Bill.

The amendment was rejected by 55 votes to 7.

"Incapable of Volition."

Subsection (3) provides that if any voluntary boarder becomes incapable of volition, he shall not be retained as a voluntary boarder for a longer period than one month, but shall, on or before the expiration of that period, be discharged.

Sir **BOYD MERRIMAN** moved to substitute for the words "incapable of volition," the words "incapable of voluntarily submitting himself to treatment." He explained that this was the first of a series of amendments which dealt with an important point which he had raised on the second reading. The Minister of Health had indicated to him that he would probably meet this point by drafting an amendment to define the words "incapable of volition," and he (Sir Boyd Merriman) was anxious to hear exactly what the meeting proposed to do. As he had pointed out on second reading, the words "incapable of volition" meant to him as a lawyer that a man was completely mad.

Mr. **GREENWOOD** said that he thought that there was a tendency to attach too much importance to the form of words. Everyone, he thought, was anxious to get a proper understanding of what the words "incapable of volition" meant, and the most convenient way would be to leave the words as they were in the Bill, and to incorporate an amendment in the definition clause later on making it quite clear what "incapable of volition" meant. He would be prepared to do that.

Dr. **VERNON DAVIES** said that this was a very difficult part of the Bill, because medically it was not easy to define what "incapable of volition" really meant. He thought that the phrase required extending; it was too compact to meet the case

Dr. **MORRIS-JONES** said that medical men of very considerable experience in mental work had expressed to him dislike of the words "incapable of volition," principally on the ground that it was a matter of opinion and not of fact. These medical men had suggested to him that the words "indifferent as to whether or not he should or should not accept treatment," would be better.

Mr. **GREENWOOD** said that he did not see anything objectionable in the phrase "incapable of volition," but he agreed that it needed definition. He would be unwilling to accept the words suggested by Dr. Morris-Jones because they were not sufficiently precise.

Lieut.-Colonel **FREMANTLE** suggested that perhaps the Minister might accept the words "incapable of expressing willingness or unwillingness to receive treatment for mental illness."

After further discussion,

Mr. **GREENWOOD** promised to look further into the matter, with a view to finding alternative words for those in the Bill, or drafting a definition of the latter words which would meet the wishes of the Committee.

The Committee adjourned.

HOUSE OF LORDS.

WEDNESDAY, FEB. 26TH.

GOVERNMENT AND SLUM CLEARANCE.

The Bishop of **SOUTHWARK** called attention to recent annual reports of medical officers of health on bad housing conditions, and asked the Government to state when it was proposed to introduce legislation dealing with the slums. He alluded to the deplorable figures as shown in the last census, and, while welcoming the fact that 1,480,000 houses had been built in England, Wales, and Scotland during the last three years, believed that the slums were as overcrowded now as they were ten years ago. Since the war he said 139 slum clearance schemes had been submitted and 121 confirmed, but only 43 had been applied, and some of these were comparatively small. The medical officer of health in nearly all the reports which he had read laid emphasis on the seriousness of the situation, while as long as the shortage of houses continued it was not possible to put closing orders into force. He believed that on the average it took eight years to carry through a slum clearance scheme, while the man who had dwelt in the overcrowded house could not, as a rule, afford the rent charged for the better accommodation. His lordship went into the figures showing that the cost of construction including site and road charges made it impossible, even with the utmost economy to let a standardised house for less than 11s. per week. In allusion to a children's rent allowance, he quoted the following proposal: that when a man had not more than 50s. a week in wages, and had to support a wife and three children, he should be allowed a shilling a week off his rent for each child until the rent reached a figure of 7s. 6d. a week. There were serious objections to such a course. It would be said that this would mean an increase in the birth-rate among those who already had unduly large families. He was doubtful whether a shilling off the rent really entered into calculations in a matter of this kind, but he would remind their lordships that the census figures showed that fertility decreased regularly as the size of the house increased, until six or seven rooms were reached, and then it remained constant. The criticisms of this proposal were no doubt very serious, but it was difficult to see where else there could be found a solution of this extremely difficult problem how to provide for the men with small wages and large families, and he hoped that the Minister of Health, in preparing his Bill, would go very carefully into that question. He also hoped the Government would give them some assurance that their legislation to deal with slums would be introduced and passed this session.

Overcrowded Slums.

The Bishop of **LONDON** said he could bear witness that at the present time the slums were as overcrowded as they had ever been. A week or two ago he went to Fulham, and inspected 13 houses in what was supposed not to be the worst slum in that area. They were verminous and filthy, and there was one large family on each of the landings. Each house had been purchased for £150, and another £150 was being spent on making it self-contained, with separate sanitary arrangements for each family. The rent the tenants paid was equivalent to 2½ per cent. on the money which was borrowed to buy the houses and carry out the improvements. That was only an illustration of what could be done by a charity; the same thing was going on all over London. But these public utility companies were only a drop in the ocean. Any Bill which might be brought in ought to make it much simpler for the ground landlord, who often had to bear the imputation of owning bad property, to get at his property. Much more encouragement ought to be given to borough councils to use their powers to deal with the slums. What was wanted really was to rouse the conscience of the country.

Lord **DARYNGTON** said that only the Government could deal with the problem, while he disputed the common statement that if the slum population were moved into better houses they would turn them into slums again.

Decrease in New Houses.

The Earl of **ONSLOW** pointed to the depressing drop in the number of houses built during the last quarter of 1928 with, he added, a slight increase in their cost. He alluded to the opportunities which the reconditioning of houses presented, holding that new powers should be given to local authorities in that direction.

Lord **MARLEY** found the reports of the medical officers of health seriously disturbing to the Government. He referred to the recruiting figures at the beginning of the war, and to the incidence of tuberculosis on slum areas, and considered that the late Government had not used its big majority to assist local authorities to carry out clearance schemes. The present Government, he said, were considering whether they should alter the questions in the next census paper, so as to obtain information enabling them to visualise the problem better, remarking that the new Bill projected by the Government would simplify and shorten the procedure dealing with slum clearance. They would make provision for the necessary capital to deal with the cost of such clearances, and they would assist local authorities in the inspection of property, and its maintenance in proper repair. They were definitely prepared to encourage proper management of property in the replaced slum areas. They would also encourage the decentralisation of industry, and the removal of factories from closely populated areas into more rural areas where town-planning would ensure that they did not interfere with the amenities of the district. It was the intention of the Government to introduce their Bill in the House of Commons very shortly.

The Archbishop of **CANTERBURY** expressed satisfaction that Lord Marley had given reason for encouragement in the hope that long-deferred legislation was now impending. The progress that had been made hitherto in dealing with the slum problem had been lamentable.

The debate was adjourned.

HOUSE OF COMMONS.

WEDNESDAY, FEB. 26TH.

International Opium Convention.

Major **HARVEY** asked the Secretary of State for Foreign Affairs whether all countries had now signed and ratified the International Opium Convention of 1925; and, if not, whether he would give the names of those abstaining.—Mr. **HENDERSON** replied: Ratifications and definitive accessions to this Convention have been deposited on behalf of 31 countries. There are 11 other countries on whose behalf signatures or accessions have been given, but which still require, before they take effect, ratification or confirmation. Twenty-five countries have neither signed nor ratified nor acceded. The following is the answer:—

Ratifications or Definitive Accessions: Austria; Belgium; United Kingdom of Great Britain and Northern Ireland (including all Colonies, Protectorates and Mandated Territories); Canada; Australia; Union of South Africa; New Zealand, Western; Samoa; India; Bulgaria; Czecho-Slovakia; Free City of Danzig (through the intermediary of Poland); Dominican Republic; Egypt; Finland; France; Germany; Greece; Italy (for the Kingdom and Colonies); Japan; Latvia; Luxemburg; Monaco; Netherlands (including Netherlands Indies, Surinam and Curacao); Poland; Portugal; Roumania; Salvador; San Marino; Kingdom of Serbs, Croats, Slovenes; Siam; Spain; Sudan; Switzerland; Venezuela. *Signatures or Accessions not yet perfected by Ratification:*—Albania; Bolivia; Brazil; Chile; Cuba; Denmark; Hungary; Irish Free State; Nicaragua; Persia; Uruguay. *The Convention is open to Accession by:*—Abyssinia; Afghanistan; United States of America; Argentine Republic; China; Colombia; Costa Rica; Ecuador; Estonia; Guatemala; Haiti; Hejaz; Honduras; Iceland; Liberia; Liechtenstein; Lithuania; Mexico; Norway; Panama; Paraguay; Peru; Union of Soviet Socialist Republics; Sweden; Turkey.

The Gas Protocol.

Mr. HASLAM asked the Secretary of State for Foreign Affairs which States had now ratified the Gas Protocol.—Mr. HENDERSON replied: The following have either ratified or definitely acceded to the Geneva Gas Protocol: the United Kingdom of Great Britain and Northern Ireland; Canada: The Commonwealth of Australia; France; Germany; Italy; New Zealand; The Union of South Africa; India; Austria; Belgium; China; Egypt; Finland; Liberia; Persia; Poland; Roumania; Spain; Union of Soviet Socialist Republics; Turkey; Venezuela; and Yugoslavia.

Emigrants to Canada Rejected on Medical Grounds.

Mr. DAY asked the Under Secretary of State for Dominion Affairs the number of persons rejected during the previous 12 months by the Canadian Government doctors as unfit for emigration to Canada.—Mr. LUNN replied: The total number of persons rejected in this country on medical examination as "prohibited immigrants" under the Canadian Immigration Law during 1929 was 1289. In addition, 9523 persons were certified owing to physical defects as unsuitable, though not prohibited, migrants, but of this number 3436 were subsequently permitted to proceed, after the Dominion authorities had satisfied themselves that the arrangements for their settlement in Canada were satisfactory, and on Feb. 21st 431 were still under consideration. The total number of persons finally rejected up to that date was, therefore, 6945. The total number of persons examined was 86,793.

Cost of the Board of Control.

Mr. ROBERT RICHARDSON asked the Minister of Health what was the cost of the Board of Control for the financial years 1928 and 1929.—Mr. GREENWOOD replied: The total cost of the Board of Control was £84,987 for 1928 and £87,418 for 1929. Included in these figures are sums of £40,506 and £42,849 respectively representing the cost of State institutions.

Discharge of Mental Patients.

Mr. ROBERT RICHARDSON asked the Minister of Health if he was aware that the Cobb Committee appointed by the Board of Control made a recommendation that Section 79 of the Lunacy Act be posted up in the waiting-rooms of public asylums with a view to informing the friends of patients, in addition to their relatives, of their rights relating to applications for discharge of which they would have otherwise been in ignorance; and would he have this recommendation carried out.—Mr. GREENWOOD replied: There are objections to a general requirement that this section should be posted up in waiting-rooms. But the rules of the Board require the managers of every institution on the admission of every rate-aided patient to send a notice embodying the substance of Section 79 of the Lunacy Act to all persons whose names appear as relatives or friends of the patient on the statement of particulars accompanying the Reception Order.

County Councils and Orthopædic Treatment.

Lieut.-Colonel ACLAND-TROYTE asked the Minister of Health whether he was aware that Section 14 (1) of the Local Government Act did not give county councils the necessary powers to deal with orthopædic cases; and, seeing that they were unable to supply special nourishment, irons, crutches, &c., or treatment in clinics except under the poor-law, which was undesirable, whether he would give this question further consideration with a view to introducing legislation on the subject.—Mr. GREENWOOD replied: I am advised that under Section 14 (1) of the Local Government Act, 1929, county councils will be able to provide clinics for the treatment of orthopædic cases, and as part of the work of the clinics to supply all necessary appliances. I am also advised that as a rule orthopædic cases do not need special nourishment as part of treatment, and that exceptional cases in which this is required should receive treatment in hospital.

Baker's Dermatitis.

Mr. CECIL WILSON asked the Home Secretary whether he could give, for 1922, 1926, 1927, and 1928 the number of cases of baker's dermatitis; whether, as between the earlier and later years, there had been any marked increase; if so, what steps were being taken to arrest the increase; and from what date the disease became notifiable under the Workmen's Compensation Act.—Mr. CLYNES replied: The numbers of cases in which bakers obtained Certificates of Disablement under the Workmen's Compensation Act from the certifying surgeons in respect of dermatitis in the years mentioned, are as follows: in 1922, 102; in 1926, 334; in 1927, 375; and in 1928, 389. The last few years, therefore, show a marked increase as compared with 1922, but this may be largely due to the new Order which came into force in January, 1923, and which relaxed considerably the conditions under which compensation for dermatitis had previously been payable. The disease was first brought under the Act by an Order dated May 6th, 1916. The main precautions against the disease are, I am advised, care of the hands and arms and scrupulous personal cleanliness, and in order to promote this, a Welfare Order was made under the Factory Acts, and came into force in May, 1927, which, among other things, requires the provision in bakehouses of suitable washing facilities and the prominent display of the official cautionary notice as to the prevention and cure of dermatitis among workers handling flour and sugar. These provisions have secured improved conditions of work and a wider knowledge of dermatitis in the industry, and should do much to arrest the incidence of the disease. I understand, also, that coöperation is being given by a joint committee consisting of representatives of the National Association of Master Bakers, Confectioners and Caterers, and the Amalgamated Union of Operative Bakers and Confectioners, which, with the assistance of one of the medical inspectors of factories, has been considering the question.

Detention of Man as a Criminal Lunatic.

Mr. REMER asked the Home Secretary why William Sidebotham, charged at the Chester assizes on the charge of murder, had been removed to Broadmoor asylum as a criminal lunatic, when the coroner's jury had returned a verdict of accidental death; and why in this case a lunatic was retained as a criminal when the coroner's jury had brought in a verdict that he was not the cause of the death.—Mr. CLYNES replied: He was removed to Broadmoor because the Assize jury found him insane upon arraignment without determining the issue of commission of murder, and because the court ordered his detention until His Majesty's further pleasure be known. This is the course authorised long ago by Parliament, and never since seriously questioned. With regard to the verdict of the coroner's jury, it is not for me to comment upon the finding of any court.

Slum Clearance Schemes.

Mr. MCKINLAY asked the Minister of Health the number of working-class dwellings in England and Wales acquired for demolition under slum clearance schemes between April 1st, 1925, and Dec. 31st, 1929, and the number of new dwellings erected in connexion with such schemes.—Mr. GREENWOOD replied: Information as to the number of working-class dwellings acquired is not available. The number of buildings which would include some buildings other than houses, acquired by local authorities in England and Wales between 1st April, 1925, and 31st Dec., 1929, in connexion with approved slum clearance schemes was approximately 10,000, and the number demolished approximately 8000. The number of new dwellings erected during the same period in connexion with such schemes, was nearly 9000.

Certified and Grade A Milk.

Mr. CHRISTIE asked the Minister of Health whether he would state his reasons for issuing an order to all producers of Certified and Grade A (T.T.) milk, forbidding them to send their animals to agricultural shows; and whether he was aware of the slur which such an order cast upon pedigree stock whose world-wide repute permitted of a valuable British export trade.—Mr. GREENWOOD replied: It came to my notice that the conditions under which animals are housed at shows at which both tuberculin-tested and untested animals are exhibited, were such as to involve a serious risk of infection to the tested animals. I therefore informed the producers concerned that I could not in future consent to the temporary withdrawal of animals from licensed herds for the purpose of sending them to a show, unless the show is restricted to tuberculin-tested cattle. I may add that before coming to this decision I consulted my right hon. friend, the Minister of Agriculture, and also the Certified and Grade "A" (Tuberculin Tested) Producers' Association.

Panel Doctors' Prescriptions.

Mr. JOWETT asked the Minister of Health in regard to the resolution of the London Insurance Committee, requesting him to impose a fine of £100 on four panel doctors for prescribing for their insured patients drugs and dressings beyond the average, although the tribunal appointed by him to consider this charge found in no individual prescription evidence of irregularity or extravagance, and reported that these practitioners were actuated by high idealism and had organised an efficient treatment centre in a neighbourhood where the chances of maintaining health were poor, and added to their Report a recommendation that any penalty should not be more than a formal one, if he would decide not to impose a fine on these panel doctors.—Mr. GREENWOOD replied: The practitioners concerned have exercised their right to make oral representations on the question what amount of money, if any, should be withheld; and I cannot anticipate the decision at which it will be my duty to arrive, after receiving the report of the persons appointed by me to hear these representations. I must not, however, be understood to accept my hon. friend's references to the report of the referees in this case as being either a complete or an accurate summary of their findings.

Mr. MILLS: Is it not a fact that panel doctors in practically every insurance area are constantly in conflict with these committees?

No answer was given.

MONDAY, MARCH 3RD.

Evidence in Pension Appeals.

Mr. LAWTHER asked the Minister of Pensions if he would, in the rehearing of cases for pensions by either ex-Service men or widows, give facilities for appellants to put forward their evidence, whether medical or lay, and in any decisions that were against the appellant give the reasons why their claims had been rejected.—Mr. F. O. ROBERTS replied: I am not quite clear as to the class of case which my hon. friend has in mind. I may say, however, generally that no difficulty is ever placed in the way of the production of fresh evidence in support of a claim. With regard to the last part of the question, I would point out that in the nature of the case it is not usually possible to intimate more than that the information furnished has not been sufficient to establish the claim.

National Health Insurance Regulations.

Mr. RHYS DAVIES asked the Minister of Health if he had in contemplation any changes in the near future in the regulations governing medical and any other benefit under the national health insurance scheme; and, if so, if he would state when such changes would be placed upon the Table of the House.—Mr. GREENWOOD replied: Draft regulations with respect to the issue of certificates for national health insurance purposes by medical practitioners, and with respect to the definition of drugs for the purposes of medical benefit, are in preparation. I cannot yet say when these regulations will be laid before Parliament under Section 93 of the National Health Insurance Act, 1924; but before this is done, 40 days' notice will have to be given, under the Rules Publication Act, 1893, of the proposal to make the regulations and of the place where copies of the draft of them may be obtained.

Ex-Service Men and Effects of Gas Poisoning.

Mr. LAWTHER asked the Minister of Pensions if, in view of the increasing number of cases coming under the consideration of war pensions committees of discharged men suffering from tuberculosis and neurasthenia for which they were not receiving pensions, and in many cases furnishing evidence of gas during the war, he would consider setting up a special commission to investigate the possibility of tuberculosis developing many years after discharge due to or arising from war service.—Mr. SHEPHERD asked a similar question.—Mr. F. O. ROBERTS replied: In dealing with individual claims each of which is carefully considered, medical officers of the Ministry are always alive to any symptoms or history of gas poisoning. Moreover, the effects of such poisoning have been the subject of special investigations by medical experts both on the staff of the Ministry and outside. The conclusions arrived at do not support the suggestion made by my hon. friend the Member for Darlington that there is necessarily a connexion between exposure to gas and the subsequent development of tuberculosis. In present circumstances I do not think that a further inquiry of the kind suggested would be justified.

Mr. LAWTHER asked whether, as the War Office Committee which was considering these claims regarded the setting up of such a commission as necessary in order that the fullest opportunity should be given of reaching an understanding on the matter, the right hon. gentleman would reconsider his decision.

Mr. ROBERTS replied that he was willing to consider any suggestion in reference to the matter. The best medical advice that he could secure had been given to him, and on that he was bound to act.

Mr. OLDFIELD asked whether, in view of the great ambiguity which arose in discussing some of these gas poisoning cases, the right hon. gentleman would always give the benefit of any reasonable doubt to the applicant.

Mr. ROBERTS replied that that was already done.

Mr. EDE asked if the Minister had consulted the French medical authorities who were in charge of the gas-mixing factories in France during the war, and who held very strong views on the question of the delayed action of gas in relation to tuberculosis.

Mr. ROBERTS: No, Sir. I have not had a chance of consulting that authority, but I will certainly take advice about it.

Major COHEN asked if the authorities of the British Legion, at Preston Hall, who had made a special study of this question, had been consulted.

Mr. ROBERTS replied in the affirmative. He said that he had the report of those experts. He had read it on more than one occasion, and had it in mind when he gave his original answer that afternoon.

Employers and Health Data of Employees.

Mr. W. G. HALL asked the Minister of Pensions whether any changes had been made in the practice of obtaining, in connexion with the consideration of pension cases, information from employers as to a man's health during his employment.—Mr. F. O. ROBERTS replied: The practice referred to has been very carefully considered by me, and it has now been laid down that in any case where boarding is required on the initiative of the Ministry (other than cases of epilepsy and tuberculosis where the practice is discontinued altogether) it is made clear to the man that if he has definite reasons against asking his employer for this information he need not do so.

Medical Boards and Tuberculosis Cases.

Mr. W. G. HALL asked the Minister of Pensions to what extent the medical boarding of men suffering from tuberculosis was undertaken during the more favourable summer months; and would he inquire as to whether this operated adversely to the pensioner.—Mr. F. O. ROBERTS replied: The medical boarding of these cases, as of all other classes of disability, is distributed as evenly as possible over the whole year. The seasonal variations in the condition of a tuberculous case are fully appreciated and are always allowed for in the assessment of pension.

TUESDAY, MARCH 4TH.

Medical Officers as Sanitary Inspectors.

Mr. MCKINLAY asked the Secretary of State for Scotland whether his attention had been drawn to the growing practice in Scotland of appointing medical officers as sanitary inspectors; and whether he would take steps to see that fully qualified sanitary inspectors were employed who were specially trained for this important work.—Mr. JOHNSTON replied: The answer to the first part of the question is in the negative. As regards the second part, I am afraid I cannot accept the suggestion that a medical practitioner who is also the holder of a diploma in public health is unqualified for the office of sanitary inspector.

Medical Report on "Red Biddy."

Mr. MCELWEE asked the Secretary of State for Scotland if he had received the medical report on red biddy; if he would reveal its contents to the House; whether he had found that red biddy was produced in any other place than Leith; and whether it was consumed in districts other than the West of Scotland.—Mr. ADAMSON replied: The medical investigation into the effect upon consumers of cheap red wine, and of such wine when mixed with methylated or other spirits, will take some time. I am informed that red wine is manufactured at Cleland and at Perth as well as at Leith, and that the consumption of red wine, whether by itself or mixed with other ingredients, is not limited to the West of Scotland.

QUEEN CHARLOTTE'S HOSPITAL.—The Prime Minister recently lent No. 10, Downing-street for a musical party in aid of the rebuilding fund of this hospital. The proceeds amounted to about £500.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. J. McA. Holmes is placed on the Retd. List with the rank of Surg. Capt.

Surg.-Lt. M. Barton to be Surg. Lt.-Comdr.

Lt. G. E. Smith is placed on the Retd. List.

ROYAL ARMY MEDICAL CORPS.

Capts. G. E. MacAlevey (prov. and remains secd.) and C. P. Chambers to be Majs.

Lts. F. M. Collins (prov.), J. A. Chapel, and F. P. M. Anderson to be Capts.

Lt. (on prob.) R. R. Leaning is confirmed in his rank.

Lt. (on prob.) J. M. Gibson is secd. under the provisions of Art. 205, Royal Warrant for Pay and Promotion.

The undermentioned to be Lts. (on prob.): W. A. Y. Knight (secd. under the provisions of Art. 205, Royal Warrant for Pay and Promotion), and A. F. Kennedy.

G. T. Drummond is granted a temp. commn. in the rank of Lt., whilst empld. as a Dental Surg.

TERRITORIAL ARMY.

Lt.-Col. (Bt. Col.) W. Lister, from Gen. List, R.A.M.C., to be Col. and to be A.D.M.S. 49th (W. Rid.) Div., vice Col. F. Whalley vacated.

Maj. H. T. Bates to be Lt.-Col. and to comd. 146th (W. Rid.) Fd. Amb.

Maj. W. J. McIntosh M.B. (from R.A., T.A. Res. of Off.) to be Capt.

Capt. C. H. A. Alderton, having attained the age-limit, relinquishes his commn.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Lt.-Cols. J. F. Dobson, H. S. Beadles, and J. D. Comrie, having attained the age-limit, retire and retain their rank, with permission to wear the prescribed uniform.

ROYAL AIR FORCE.

J. Murphy is granted a temporary commission as a Flying Officer.

Flight Lt. J. P. Hederman is transferred to the Reserve, Class Dii.

Flight Lt. J. McM. Wilder relinquishes his permanent commission on transfer to the Indian Medical Service.

INDIAN MEDICAL SERVICE.

Col. J. D. Graham to be Maj.

Saiyed Wasiul Hassan Askari is granted a temp. commn. in the rank of Lt.

Maj. G. Y. Thomson retires.

Col. C. L. Isaac, Asst. Dir. of Med. Servs., 53rd (Welsh) Div., T.A., is apptd. Hon. Surg. to The King, vice Col. F. G. Proudfoot (retd.).

SOUTHPORT INFIRMARY.—The annual report states that the appeal for funds on behalf of the extension of this hospital has not secured adequate support. Up to the end of 1929, the total promises only amount to £6562, and of this amount £5031 has been received towards an expenditure of nearly £50,000. The total income for the year was £10,904, and the expenditure £18,420. The workpeople's contributory scheme realised £2687. The number of motor accident cases treated was 67. The total cost to the infirmary was £970, and of this amount £189 was received, leaving a loss of £780.

BIRMINGHAM HOSPITALS.—During 1929 extensions comprising 62 additional beds were made to Birmingham Children's Hospital, together with an isolation block for infectious cases, complicated with medical and surgical conditions, and for children extremely ill who have been in contact with infection, whose admission to the general wards would be a danger to the other children. The pressure upon the hospital is so great that in August last nearly 1200 children were awaiting tonsil and adenoid operations, and the general waiting-list of major operations numbered 400. In almost every department the work done has exceeded all previous records. A nurses' home and an infants' block are badly needed, and it is proposed that the former should be proceeded with at a cost of £45,000.—The Birmingham Hospital Saturday Fund has decided to build a new convalescent home for women in view of the fact that the demand upon the existing institutions is eight times the available accommodation. Last summer women had to wait for from five to seven weeks for admission.

Medical News.

UNIVERSITY OF LONDON.—Prof. L. T. Hogben, D.Sc., has been appointed as from August 1st, 1930, to the University Chair of Social Biology tenable at the London School of Economics.

Dr. Hogben gained a first-class in the Part I. of the Natural Science Tripos in 1915, and in 1921 he obtained the D.Sc. degree of London University in Zoology, and in 1922 he became Mackinnon Student of the Royal Society, and from 1922–23 Assistant Director of the Animal Breeding Research Department. From 1923–25 he was Lecturer in Experimental Physiology in the University of Edinburgh, and from 1925–27 Assistant Professor of Zoology at McGill University. Since 1927 he has been Professor of Zoology in the University of Cape Town.

Dr. Francis Davies has been appointed as from August 1st to the University Readership in Anatomy tenable at King's College.

Dr. Davies was educated at Cardiff University and continued his medical studies at University College Hospital, London, where since 1927 he has been Senior Demonstrator in Anatomy.

The Geoffrey E. Duveen Travelling Studentship in Oto-Rhino-Laryngology, of the value of £450, has been awarded for 1930 to C. S. Hallpike, M.B.

Mr. Maurice Webb, C.I.E., has been appointed Secretary to the Senate.

He was educated at St. Paul's School and at Corpus Christi College, Oxford. He has served for 25 years in the Indian Civil Service and has been Chief Government Whip in the Legislative Assembly under the Government of India.

Mr. S. J. Worsley, D.S.O., has been appointed Academic Registrar.

He was educated at the County School, Bodmin, at University College, Nottingham, and at King's College, London. In December, 1923, he was appointed senior secretary in the Academic Department of the University and Deputy Academic Registrar, and since March, 1928, he has been Deputy Education Officer, Hampshire.

The title of Fellow of University College has been conferred, among others, on Mr. Harold Muir Evans, surgeon to Lowestoft Hospital; who has carried out research on the Nature of Fish Venom; Mr. George Samuel Sansom, D.F.C., D.Sc., honorary Research Assistant in Embryology; and Mr. Gwynne Evan Owen Williams, F.R.C.S., Vice-Dean of University College Hospital Medical School.

The title of Honorary Fellow of University College, London, has been conferred, among others, on Prof. Henry Tonks, F.R.C.S., Slade Professor of Fine Art in the University.

INSTRUCTION FOR D.P.M.—The second part of the course for the Diploma in Psychological Medicine begins this week at the Maudsley Hospital, Denmark Hill, London, S.E.5. Lectures will be held until the end of May, and inquiries should be addressed to the Director of the Central Pathological Laboratory at the Hospital. A limited number of clinical appointments are available.

"LEICESTER CITY GENERAL HOSPITAL."—When, on April 1st, the City Council of Leicester take over North Evington Poor-law Hospital, it will be renamed the "City General Hospital." It is hoped that there will be between 100 and 200 beds available there to relieve the pressure upon Leicester Royal Infirmary, which always has a long waiting-list. The mental and senile cases will be removed elsewhere, and eventually 400 or 500 beds may be available.

A TOUR IN CZECHO-SLOVAKIA.—A tour through Czecho-Slovakia is projected in which a limited number of medical men are invited to participate, the intention being to visit certain medical spas as well as interesting centres from the historical and picturesque point of view. The start will be made on Monday, April 14th, from Liverpool-street, London, and the itinerary is timed so that the tourists will arrive back at that station on Monday, May 5th. The railway journeys in Czecho-Slovakia will mostly be made in a car at the disposal of the party, which will be hitched on and off the trains, but the first half of the trip may be made by automobile. Among the places mentioned to be visited, as well as Prague, are Teplice-Šanov, Marienbad, Pilsen, Lubačovice, Carlsbad, Jáchymov, and Franzensbad. Three days will be devoted to the visit to Prague, and it is suggested that the party may reach Macocha in Moravia, Brunn, Pištany, the Sonntag Sanatorium, and Tatras. The return journey is planned by way of Dresden. The total cost of the trip is estimated to be under £40, exclusive of the usual extras, and the travellers will be accompanied by an English-speaking doctor from the Czecho-Slovak Ministry of Health, and by a railway official who will be in charge of the luggage and the transport. Further information can be obtained from Mr. Henry Baerlein, the Bath Club, 34, Dover-street, London, W.

UNIVERSITY OF MANCHESTER.—Prof. F. E. Tylecote, F.R.C.P., has been elected Chairman of Convocation for the ensuing year.

OPHTHALMOLOGICAL SOCIETY.—To celebrate the fiftieth anniversary of this society a banquet will be held at the hall of the Fishmongers Company, London Bridge, at 7.30 for 8 P.M., on Friday, April 4th.

MACEWEN MEMORIAL LECTURE.—The second lecture under the Macewen Memorial Foundation was given at Glasgow on Feb. 28th by Sir Charles Ballance, who took as his title the Dawn and Epic of Neurology and Surgery.

HARVEIAN SOCIETY OF LONDON.—The Harveian lecture, entitled *Should Medicine be a Mendicant?* will be delivered by Prof. E. W. Hey Groves, of Bristol, at 8.30 P.M. on Thursday, March 13th, at 11, Chandos-street, Cavendish-square, and not at Paddington Town Hall as previously advertised. It is announced that visitors will be welcome

THE annual meeting of the Royal Medical Benevolent Fund will be held at the Rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, W.1, at 5 P.M. on Monday, March 10th. Sir Thomas Barlow, will preside. The annual report and statement of accounts for the year ended Dec. 31st, 1920, will be submitted, and the election of officials and committee of management for the ensuing year will take place.

APPOINTMENTS AT THE MINISTRY OF HEALTH.—We understand that the following medical men have been appointed to the staff of the Ministry of Health: Dr. Eric Donaldson, medical officer of health for Bognor urban district; Dr. Neil Robertson Beattie, chief assistant medical officer of health for Willesden urban district; Dr. Thomas Steven McIntosh, medical officer of health for Hendon; and Dr. Norman Fairbanks Smith, lately of the Kitchener School of Medicine, Khartoum, and of Madeira.

POST-GRADUATE NEUROLOGICAL STUDY.—Under the auspices of the American Medical Association of Vienna a special course in English will be held again this year, from June 23rd to July 31st, at Prof. Wagner-Jauregg's neuro-psychiatric clinic (of which the director is now Prof. Pötzl), and at the neurological institute of Prof. Marburg. It is proposed that the whole sphere of neurology and psychiatry and allied subjects shall be covered in 204 hours' instruction. Particulars may be had from Dr. E. Spiegel, Vienna I, Falkestrasse 3.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Particulars of the week's programme will be found in our Medical Diary. Two special courses start on Monday, March 10th. The first is a week's course at the Hospital for Consumption and Diseases of the Chest, Brompton, from 10 A.M. to 4 P.M. *daily*, and the second, at the Royal National Orthopædic Hospital until *March 22nd, begins with* operations each morning at 9 A.M. or 10 A.M. and includes out-patient clinics in the afternoon. Other courses beginning in March are as follows: *March 17th to April 12th*, neurology at the West End Hospital for Nervous Diseases, daily at 5 P.M. March 17th to April 12th, venereal disease at the London Lock hospital, every afternoon and *evening*; March *24th to April 12th*, medicine, surgery, and gynæcology at the Royal Waterloo Hospital, all day; March 31st to April 5th, *gastro-enterology* at the Prince of Wales's Hospital, Tottenham, all day. Copies of syllabuses and full information is obtainable from the Secretary of the Fellowship, at 1, Wimpole-street, London.

NORTH OF ENGLAND DERMATOLOGICAL SOCIETY.—The first annual general meeting of this society was held in Manchester on Feb. 7th, with Dr. Louis *Savatard, the President, in the chair.* The following officers were appointed for 1930:—President: Rupert Hallam. Vice-Presidents: G. H. Lancashire, R. Stopford *Taylor. Hon. Secretary:* P. Brooke Mumford. Other Members of Council: W. Dyson, J. T. Ingram, E. F. Skinner. Editor: L. Savatard.

DONATIONS AND BEQUESTS.—Among other bequests the late Mrs. Annie Davey of Falmouth, left £1000 to the Falmouth Sailors' Home and Hospital £500 to the Falmouth Cottage Hospital; £300 each to the Bristol General Hospital, the Bristol General Infirmary, the Bristol Hospital for *Women and Children*, the Bristol *Dispensary*.—Mr. James Hutchison, of Chilwell Beeston, Notts, who left £7042, gave £200 each to nurses who attended him at Barnes Convalescent *Home*, Cheadle, and after other bequests the residue of the property to the Medical Faculty of Glasgow University, "*my alma mater*."—Under the will of Mrs. Ann Moulds, of St. Helens-road, Leigh, Lancs, the whole of her estate, about £6000, has been bequeathed to Leigh Infirmary.—Lord Forteviot, of Dupplin Castle, Perthshire, left £10,000 to Perth Royal Infirmary.

ROYAL INSTITUTION.—At a general meeting on March 3rd it was announced that the managers had *elected* Mr. J. B. S. Haldane Fullerian Professor of Physiology in succession to Mr. J. S. Huxley.

UNIVERSITY OF LONDON MEDICAL GRADUATES SOCIETY.—The first meeting and dinner of London graduates resident in Manchester and district was held on *Feb. 28th* at the Midland Hotel, Manchester, with Sir StClair Thomson, the President, in the chair.

UNIVERSITY OF GLASGOW.—On March 4th Sir Donald MacAlister was installed as Chancellor of the University in succession to the late Lord Rosebery. Among those on whom he conferred the honorary degree of LL.D. was Sir George Newman, chief medical officer of the Ministry of Health.

LONDON HOSPITAL MEDICAL COLLEGE.—A course in Advanced Medicine suitable for candidates preparing for the M.D. and M.R.C.P. Examinations will begin on *April 28th. Further* particulars may be obtained on application to the Dean, Prof. William Wright, at the hospital.

RADIOGRAPHY OF TUBERCULOSIS.—The Joint Tuberculosis Council (Tavistock House, North Tavistock-square, London, W.C.1) have arranged a post-graduate course in the X ray department of the Hospital for Consumption and Diseases of the Chest, Brompton, S.W., from Monday, *March 17th, to* Saturday, the 22nd. The course will be conducted by Dr. Stanley Melville and others, and will be limited to 25 members. Details may be had from the hon. secretary.

CONGRESS ON PHYSIOTHERAPY.—The Fifth International Congress on Physiotherapy will be held from Sept. 14th to 18th at Liége, where the centenary of the independence of Belgium is to be celebrated at that time. Twenty-five countries have appointed national committees, and the chief subjects of discussion will be the *Rôle of* Physiotherapy in the Treatment of Rheumatic Disorders, Physiotherapeutic Treatment of Disorders of the Central Nervous System, and the University Teaching of Physiotherapy. Members of the Congress will be allowed to take part in the second annual meeting of the International League against Rheumatism, which is to take place at Liége from Sept. 18th to 20th. The hon. secretary of the British Section of the Congress is Dr. W. Kerr Russell, 126, Harley-street, London, W.1.

REDHILL HOSPITAL.—The annual report of the medical superintendent, Dr. J. Nissen Deacon, shows an increase in the work of this Edgware hospital at present belonging to the Hendon Board of Guardians, which was opened two years ago, and serves a district of some 50 square miles. It was intended primarily to meet the growing demand for the treatment of acute medical and surgical cases, and for maternity cases occurring amongst the sick poor of the Hendon Union. Last year the number of cases treated to a conclusion was 2565, an increase of 777. The number of surgical cases was more than double that of medical cases. Many of the casualties were traffic accidents, and 190 of them were fractures needing a long stay in the wards.

NEW PREMISES FOR MESSRS. H. K. LEWIS AND CO., LTD.—Under an agreement with the University of London, University College, Messrs. H. K. Lewis are erecting a new building on the side of 134, Gower-street, of which they will occupy the basement, ground and first floors, the three upper floors being occupied by the College, with a separate entrance and stairway from Gower-street. When this building is completed, probably by next year, it has been arranged that the Company shall use the whole of the building, while their old premises of 136, Gower-street and 24, Gower-place, are pulled down. On this site a new building will be erected by the company in general conformity with the new premises on No. 134, and the rest of the College buildings in Gower-street. A brief outline of the facts of the scheme will serve to contradict an impression that the familiar position on the corner of Gower-street and Gower-place has been parted with by the firm. While they are in occupation of No. 134 there will be many temporary difficulties to contend with, but plans are being carefully considered to ensure that these difficulties shall be overcome. But some sacrifice of space and convenience on the company's own site at the corner has been made to architectural necessities in order to secure a satisfactorily artistic effect in carrying out the general design. The scheme originated shortly after the late Prof. Simpson's retirement from the Chair of Architecture at University College, and he prepared the first plans. His son, Mr. J. R. Moore Simpson, A.R.I.B.A., has designed the building now to be erected.

A REGISTER OF SPAS.—At the annual meeting of the British Spas Federation, held recently in London, it was reported that an international and national register of spas of the world is being prepared under the ægis of the International Society of Medical Hydrology, the intention being to provide for all medical men the scientific and relevant data of each spa in such a concise form as will afford an easy method of comparison of their value. Analyses of the waters are to be expressed in standardised terms. The Federation, in support of this scheme, is instructing its members to arrange that all analyses be prepared in the prescribed manner.

It is stated that British spas generally report an increased number of visitors for treatment during 1929, and in several instances this increase was about 20 per cent. above the average numbers of the three previous years. Arrangements are being made for the immediate publication of a new medical handbook, available only for members of the medical profession.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

THE ROYAL SOCIETY, Burlington House, Piccadilly, W.

Thursday, March 13th.—4.30 P.M., The *following papers will be read*:—V. B. Wigglesworth: A Theory of Tracheal Respiration in Insects. (Communicated by Sir Walter Fletcher.) H. Raistrick, and others: Studies in the Biochemistry of the Lower Fungi. (Communicated by Sir Frederick Hopkins.)

ROYAL INSTITUTION, 21, Albemarle-street, W.

Tuesday, March 11th.—5.15 P.M., Dr. Charles Singer: Science in the Middle Ages.

Thursday.—5.15 P.M., Mr. J. B. S. Haldane: Some Problems of Genetics.

Friday.—9 P.M., Prof. G. Elliot Smith: New Light on Vision.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Monday, March 10th.—5 P.M., UNITED SERVICES. Major John Hare, R.A.M.C.: Ear Diseases in Relation to the Services.

Tuesday.—5 P.M., THERAPEUTICS AND PHARMACOLOGY. Preliminary Communication: Prof. E. C. Dodds and Dr. J. D. Robertson: Observations on the Therapeutic Effects of the Œstrus-producing Hormone. A discussion will follow. 8.30 P.M., PSYCHIATRY. Joint Meeting with the British Psychological Society. *Discussion on the Rôle of Psychotherapy in the Treatment of the Psychoses.* Speakers: Dr. H. Devine, Dr. Edward Glover, Dr. R. D. Gillespie, and Dr. H. Yellowlees.

Thursday.—8.30 P.M., NEUROLOGY. (Cases at 8.15 P.M.) Discussion on Injuries to the Brachial Plexus. Cases illustrating such injuries will be shown.

Friday.—5.30 P.M., CLINICAL. (Cases at 4.30 P.M.) Sir James Dundas-Grant: Vertigo and Epileptiform Seizures Completely Arrested by Ossiculectomy. Attic Cholesteatoma with Vertigo; Ossiculectomy. *Relief from Vertigo. Asthma in a Child* Relieved by Removal of Redundant Portions of the Middle Turbinated Bodies. Dr. C. Worster-Drought: Deformities of Hands and Feet Following Several Attacks of Acute Rheumatism. Mr. Cecil P. G. Wakeley: Endothelioma of the Pleura. Gumma of the Testicle. Dr. H. S. Stannus: Case of Tetany. Dr. Maurice Cassidy: Aneurysmal Dilatation of the Left Auricle. Atypical Leukæmia. Dr. F. E. Saxby Willis: Further Report on Case of Tumour of Lung. 5 P.M., OPHTHALMOLOGY. Clinical Meeting at Guy's Hospital (Ophthalmic Out-patients' Department), London, S.E. Mr. E. R. Chambers: Leontiasis Ossea. Other cases will be shown.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, March 10th.—8.30 P.M., Discussion on Cardiac Infarction, to be introduced by Dr. J. W. McNee.

MEDICAL SOCIETY FOR THE STUDY OF INDIVIDUAL PSYCHOLOGY, 55, Gower-street, London, W.C.

Thursday, March 13th.—8.30 P.M., Dr. Inman: The Psychological Aspect of Eye Symptoms.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

Wednesday, March 12th.—8 P.M., Prof. G. Elliot Smith: The Human Brain.

BIOCHEMICAL SOCIETY.

Friday, March 14th.—3 P.M. (in the Department of Physiology and Biochemistry, University College, Gower-street, W.C.) Communications: R. A. McCance and K. Madders, The Comparative Rates of Absorption of Certain Sugars from the Human Intestine. A. Hunter and J. A. Dauphinee, The Rate of Liberation of Arginine in the Tryptic Digestion of Proteins; A. Harden and and M. G. Macfarlane, Fermentation by Yeast Preparations. G. F. Marrian and P. F. Marrian, Microdeterminations of Hydroxyl Groups by Grignard's Reagent. G. F. Marrian, Further Observations on the Alcohol Isolated from the Urine of Pregnancy; An Improved Method for the Preparation of Œstrin—The Isolation of Active Crystalline Material from Urine. B. Ahmad and J. C. Drummond, Observations on the Relation of Carotene to Vitamin A. L. F. Hewitt, Oxidation-reduction Potentials of Cultures of Hæmolytic Streptococci. C. A. Ashford, The Phosphorus Distribution in Blood During Hypervitaminosis. R. A. Morton, I. M. Heilbron, and A. Thompson, Some Further Observations on Vitamin A. R. A. Morton and I. M. Heilbron, A note on the Vitamin A of Butter. T. Moore, The Conversion of Carotene to Vitamin A in vivo. F. Dickens, The Preparation and Properties of an Active Principle from the Urine of Pregnancy. K. H. Coward, K. M. Key, R. Morgan, and F. J. Dyer, Variation in Vitamin A Assay.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

Tuesday and Thursday, March 11th and 13th.—5 P.M., Dr. Donald Hunter: The Significance to Clinical Medicine of Studies in Calcium and Phosphorus Metabolism. (Goulstonian Lectures.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, March 10th, to Saturday, March 15th.—MEDICAL SOCIETY LECTURE ROOM, 11, Chandos-street, Cavendish-square, W. Tues., 4 P.M., Lecture by Mr. W. Girling Ball on the Differential Diagnosis and Treatment of Infections of the Urinary Tract. No fee.—CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. Mon., 2 P.M., Demonstration (Gynæcological Operations) by Mr. J. Bright Banister. No fee.—ST. JOHN'S HOSPITAL, Leicester-square, W.C. Tues., 6 P.M., Demonstration (Dermatological) by Dr. J. E. M. Wigley.—HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Brompton, S.W. Special Post-graduate Course in Diseases of the Chest, all day for one week.—ROYAL NATIONAL ORTHOPÆDIC HOSPITAL, Great Portland-street, W. Special Post-graduate Course in Orthopædics, occupying all day for two weeks.—ST. JOHN'S HOSPITAL, Leicester-square, W.C. Special Post-graduate Course. Daily clinical work every afternoon and evening. Tues. and Thurs. *Further* particulars from the Fellowship of Medicine.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

Monday, March 10th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

Tuesday.—2.30 to 5 P.M.: Medical, Surgical, Ear, Nose and Throat Clinics. Operations.

Wednesday.—2.30 to 5 P.M.: Medical, Skin and Eye Clinics. Operations.

Thursday.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, Nose, Throat, and Ear Clinics. Operations.

Friday.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases. Clinics. Operations.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James Hospital, Ouseley-road, Balham, S.W.

Wednesday, March 13th.—4 P.M., Dr. N. Bruce Williamson: The Arrhythmias in General Practice.

UNIVERSITY COLLEGE, Gower-street, W.C.

Monday and Wednesday, March 10th and 12th.—5.15 P.M., Prof. Otto Meyerhof: Chemistry of Muscle. (Last two lectures.)

Tuesday and Thursday, March 11th and 13th.—5 P.M., Prof. J. C. Brash: The Growth and Developmental Mechanics of Bone. (Public lectures.)

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL, Gower-street, W.C.

Monday, March 10th.—4.15 P.M., Dr. Charles Singer: The History of our Knowledge of the Mechanism of Heredity.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark Hill, S.E.

Thursday, March 13th.—9 P.M., Dr. M. Critchley: The Chronic Epileptic.

ROYAL NORTHERN HOSPITAL, Holloway.

Wednesday, March 12th.—3.15 P.M. (at the Royal Chest Hospital), Dr. H. B. Day: Artificial Pneumothorax Treatment.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL.

Friday, March 14th.—4 P.M., Mr. Archer Ryland: Musculature of the Vocal Cords.

NATIONAL HOSPITAL POST-GRADUATE COURSE, Queen-square, W.C.

Monday, March 10th.—12 noon, Dr. Greenfield: Pathology of Nervous System. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Kinnier Wilson: Neurotubercle.

Tuesday.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Bernard Hart: Disorders of Personality.

Thursday.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Purdon Martin: *Localising* Signs of Tumours in the Cerebral Hemispheres.

Friday.—12 noon, Dr. *Purdon* Martin: Anatomy and Physiology of Nervous System. 2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Walshe: Peripheral Neuritis.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

Tuesday, March 11th.—5 P.M., Dr. J. E. M. Wigley: Leukæmia Cutis, Mycosis Fungoides.

Thursday.—5 P.M., Dr. J. E. M. Wigley: Pemphigus and Allied Eruptions.

ROYAL DENTAL HOSPITAL OF LONDON, Leicester-square, W.C.

WEDNESDAY, March 12th.—6 P.M., Mr. I. H. Maclean: Rosenow's Theory of Elective Localisation: Its Significance in General Streptococcal Disease Associated *with Dental Sepsis.*

ANCOATS HOSPITAL POST-GRADUATE COURSE, Mill-street, Manchester.

THURSDAY, March 13th.—4.15 P.M., Mr. E. E. Hughes: Prostatic Enlargement.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, March 11th.—4.15 P.M., Dr. A. Ramsbottom: Enteritis with Pyrexia.

FRIDAY.—4.15 P.M., Mr. J. Morley: Demonstration of Surgical Cases.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

FRIDAY, March 14th.—3.30 P.M. (at the Royal Infirmary), Dr. A. B. Nutt: Eye Symptoms in Renal Diseases.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION.

WEDNESDAY, March 12th.—4.15 P.M. (at the Western Infirmary), Dr. J. G. Macgregor Robertson: Venereal Diseases (Male).

Appointments.

BLACKWOOD, MARGARET, M.B., Ch.B. Glasg., D.P.H. Liverp. has been appointed Assistant Medical Officer of Health Barnsley.

CHANDLER, F. G., M.D. Camb., F.R.C.P. Lond., Assistant Physician to St. Bartholomew's Hospital.

NICHOLSON, RUTH, M.B., M.S. Durh., D.P.H., Hon. Surgeon to the Liverpool Maternity Hospital.

SAVIN, L. H., M.B., B.S. Lond., F.R.C.S. Eng., Ophthalmic Surgeon to the Metropolitan Hospital.

City of London Maternity Hospital: LOVE, R. J. MCN., M.S. Lond., F.R.C.S. Eng., Consulting Surgeon; CHARLES, H., L.R.C.P. Lond., M.R.C.S., and RICHARDS, H. A., L.R.C.P. Lond., M.R.C.S., Anæsthetists.

Vacancies.

For further information refer to the advertisement columns.

Albert Dock Hospital, Connaught-road, E.—M.O. At rate of £110.

All Saints' Hospital for Genito-Urinary Diseases, 91, Finchley-road, N.W.—Three H.S.'s. Each at rate of £150.

Aylesbury, Royal Buckinghamshire Hospital.—Res. M.O. At rate of £180.

Ayr County Hospital.—H.S. £150.

Barnsley, Beckett Hospital and Dispensary.—Jun. H.S. £140.

Barrow-in-Furness, North Lonsdale Hospital.—H.S.'s, each £150.

Bath, Royal United Hospital.—H.S. At rate of £150.

Bedford County Hospital.—Asst. H.S. £130.

Birmingham and Midland Eye Hospital.—Res. Surg. O. £150.

Birmingham, Dudley-road Hospital.—Jun. Asst. M.O.'s. All at rate of £200.

Birmingham Ear and Throat Hospital.—H.S. At rate of £150.

Birmingham General Hospital.—Res. Surg. Reg. £100–£20–£140.

Birmingham, Queen's Hospital Medical School.—Three H.P.'s. H.S. Anæsthetist. Also Dental H.S. Each £70.

Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £100.

Brighton, Royal Sussex County Hospital.—Hon. Clin. Asst. for Ophth. Dept. Also H.S. £150.

Burnley, Victoria Hospital.—H.P. At rate of £125.

Cambridge, Addenbrooke's Hospital.—H.P. Also Two H.S.'s. Each at rate of £130.

Cardiff Royal Infirmary.—H.S. to Ophth. Dept. At rate of £75.

Carlisle City.—Asst. M.O.H. £750.

Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C.—Two Hon. Assts. to Out-Patient Dept.

Chester County Mental Hospital.—4th Asst. M.O. £350.

Colonial Medical Services.—Medical Officers.

Connaught Hospital, Orford-road, E.—Sen. Res. M.O. At rate of £150. Also Res. H.S. and H.P. Each at rate of £100.

Derby, Derbyshire Royal Infirmary.—Ophth. H.S. £150.

Dreadnought Hospital, Greenwich.—H.P. and H.S. At rate of £110.

Dudley, Guest Hospital and Eye Infirmary.—Asst. H.S. £150.

Edinburgh Hospital for Crippled Children.—Surgeon. £1000.

Edinburgh Royal Infirmary.—Tutor and Sen. Clin. Asst. for Ophth. Dept. £145.

Exeter City.—Asst. Tuber. O. and Asst. M.O.H. £600.

Freemasons Hospital and Nursing Home, 237, Fulham-road, Chelsea, S.W.—Radiologist.

Great Yarmouth General Hospital.—H.S. £150.

Grocers' Company Research Scholarships.—Each £300.

Hertfordshire County Council, County Sanatorium, Ware Park.—Asst. M.O. £300.

Hospital for Tropical Diseases, Endsleigh Gardens, W.C.—Two H.P.'s at rate of £150.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W. Asst. Phys.

Hove Hospital, Sackville-road.—Res. M.O. £150.

Hove, Lady Chichester Hospital.—Jun. H.P. At rate of £50.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Inverness, Northern Infirmary.—H.P. and Jun. H.S. £100.

Ipswich, East Suffolk and Ipswich Hospital.—Two H.S.'s. Each £120.

Kensington, Fulham, and Chelsea General Hospital, 194, Finborough-road, Earl's Court, S.W.—Res. Cas. M.O. At rate of £100.

Leeds Public Dispensary.—Jun. Res. M.O. £150.

Leicestershire and Rutland Mental Hospital, Narborough.—Med. Supt. £800.

Liverpool, Hahnemann Hospital, Hope-street.—Res. M.O. At rate of £100.

Liverpool Open-air Hospital for Children, Leasowe.—Jun. M.O. £150.

Liverpool, Royal Southern Hospital.—H.P., H.S., and M.O. Each £60. Also Cas. O. £100.

Liverpool, St. Paul's Eye Hospital.—H.S. At rate of £120.

London Hospital.—Director of Dept. for Venereal Diseases. £800.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Jun. Res. M.O. At rate of £50.

Manchester Royal Children's Hospital, Pendlebury.—Asst. Phys. £50.

Manchester, St. Mary's Hospitals.—Four H.S.'s to Special Depts. Each at rate of £50.

Manor House Hospital, Golders Green, N.W.—H.S. at rate of £200.

Middlesex Hospital, W.—Ferens Institute of Otolaryngology, Bernhard Baron Research Studentship. £300.

Newcastle-on-Tyne Hospital for Sick Children.—Jun. H.S. at rate of £100; also Res. Sen. H.S. and Res. H.P., each at rate of £95.

New Zealand, Auckland Hospital Board.—Med. Reg. Also Surg. Reg. Each £600.

New Zealand, Wellington General Hospital.—Radiologist. £900.

Nottingham City Infirmary.—Res. Med. Supt. £900.

Nottingham General Hospital.—2nd Cas. O. At rate of £150.

Poplar, Metropolitan Borough of.—Temp. Asst. to M.O.H. £600.

Royal Northern Hospital, Holloway, N.—Res. M.O. £200.

St. John's Hospital, Lewisham, S.E.—Res. H.S. £100.

St. Mary's Hospital, W.—Sen. and Jun. Clin. Assts. £100 and £50 respectively.

Salford City.—Jun. Asst. for Venereal Diseases Centre. £500.

Salford City Infectious Diseases Hospital.—Jun. Asst. Res. M.O. £200.

Salford Royal Hospital.—H.P., Two H.S.'s, also Cas. H.S. All at rate of £125.

Scarborough Hospital and Dispensary.—Two H.S.'s. At rate of £126.

Sheffield Royal Infirmary.—Ophthalmic H.S. At rate of £80.

Shoreditch Metropolitan Borough.—Asst. M.O.H. £650.

Southampton Children's Hospital and Dispensary for Women.—Res. M.O. At rate of £100.

Southampton, Royal South Hants and Southampton Hospital.—Jun. H.S. Also Cas. O. At rate of £140 and £130 respectively.

South London Hospital for Women, South Side, Clapham Common, S.W.—H.P., and 3 H.S.'s, each at rate of £50.

Stepney Metropolitan Borough.—M.O.H. &c. £1200.

Stirling District Mental Hospital, Larbert.—Jun. Asst. M.O. £300.

Stockport Infirmary.—Res. Surg. O. £250.

Truro, Royal Cornwall Infirmary.—H.S. £170.

Wakefield, Clayton Hospital.—Two H.S.'s. At rate of £150.

Walsall General Hospital.—Cas. H.S. At rate of £120.

West London Hospital, Hammersmith-road, W.—Hon. Asst. Surg., Hon. Med. Reg., and Hon. Obstet. Reg.

Westminster Hospital, Broad Sanctuary, S.W.—Sen. Res. and Cas. O. Also Asst. Med. Reg. At rate of £104 and £100 respectively.

Woolwich and District War Memorial Hospital, Shooters-hill.—H.P. and H.S. Each at rate of £125.

York County Hospital.—H.S. £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Morpeth (Northumberland) and Matlock (Derby).

Births, Marriages, and Deaths.

BIRTHS.

HUDDY.—On Feb. 26th, the wife of G. P. B. Huddy, M.S., F.R.C.S., of Dudley-road Hospital, Birmingham, of a son.

MACDONNELL.—On Feb. 23rd, at 89, Lower Baggot-street, Dublin (*Nursing Home*), the wife of J. J. MacDonnell, M.D., of Avoca, Hook, Surbiton, of a daughter.

SUMMERS.—On Feb. 28th, at a nursing home, the wife of Ralph D. Summers, M.R.C.S., L.R.C.P., of a son.

MARRIAGES.

BEAN—GOW.—At the Parish Church of All Souls', South Hampstead, London, on 26th Feb., 1930, Kenneth Dobing Bean, M.B., Ch.B., of Cheadle, Cheshire, second son of the late Rev. Benjamin and Mrs. Bean, of Homedale, Sutton, Surrey, to Kathleen Bruce, daughter of Allen Bruce Gow, Esq., of 66, Compayne Gardens, Hampstead.

DEATHS.

FRIPP.—On Feb. 25th, at West Lulworth, Alfred Downing Fripp, K.C.V.O., C.B., M.S., F.R.C.S., Hon. Surgeon to His Majesty the King and to H.R.H. The Duke of Connaught, Consulting Surgeon to Guy's Hospital, aged 64.

REDMOND.—On Feb. 15th, at Vancouver, British Columbia, William Redmond, L.R.C.S. Edin., L.R.C.P. Lond., late Fleet-Surgeon, Royal Navy, in his 91st year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

TYPES OF PERSONALITY, WITH SPECIAL REFERENCE TO INDIVIDUAL PSYCHOLOGY.

Remarks made during a Lantern Demonstration given to the York Medical Society on Feb. 8th, 1930,

BY F. G. CROOKSHANK, M.D., F.R.C.P.

THOSE who have the leisure, the opportunity, or the inclination to look away sometimes from the official, or academic medicine of the schools, the text-books, and the examination room, are aware of two distinct tendencies displayed by those now engaged in breaking new ground, or in clearing the jungle-growth that has encumbered old highways of medical thought. These will, in their turn, become orthodox and conventionalised, but for the moment they are better appreciated by those who are discontented with Established Medicine than by those who uphold the Establishment or form part of it.

In the absence of recognition of these tendencies by Established Medicine, there is bound to be increasing flight towards Christian Science, Osteopathy, Nature Cures, Mind Cures, and the like. This, already attaining imposing dimensions, will only be checked when Academic Medicine recognises that it has no greater claim to absolute validity than has Official Art, Official Theology, or Official Economics. Already the cry for our disestablishment is becoming heard, even in Parliament!

The *first* of the tendencies alluded to is towards revolt against the conventional system, in force since Linnaeus, of diagnosing in terms of what are called Diseases: that is, suppositious or clinical entities. The *second* is towards belief in the futility of any system of Medicine that, based upon necrological research in the post-mortem room and veterinary experimentation in the laboratory, totally neglects *human nature*—for that is what we *should* mean when we say "Psychology."

We have no right to speak as if *diseases* were the primary objects of our attention. Diseases only exist subjectively, in the mind like *Virtues*, and *Vices*: they are fictions we have invented for our special purposes. The "clinical entities" are the patients themselves, who are ill, in different kinds of ways and for different reasons. Particular cancers and broken legs and fatty livers have real existence, of course, just as have pretty mouths and ugly noses. But Cancer, Influenza, Pneumonia, and so forth, have no greater claim to be called *entities*, or objects in Nature with fixed characters, than have Beauty, Truth, Murder, and Lust. Still, while it remains true, as when Peter first said it, that *il n'y a pas de maladies; il n'y a que des malades*, the conventional method of diagnosing in terms of the fictitious entities we call Diseases has for many years been *useful*. It certainly was very useful so long as we could define Diseases in terms of morbid anatomy; it seemed to have long years of usefulness before it when it was thought that we would be able to define them all in terms of bacteria. It is still sometimes useful, just as it is useful for us to pay our gas bills on the basis of the fictitious entities the Gas Companies call therms. But, unless we can make up our minds in what terms, or how to define Diseases, it will soon become a source of great mental discomfort. I do not know one clinical teacher who cares to tell his students what "a Disease" really is, or how to distinguish one from a diathesis! The fact is, to adapt Bob Acres' aphorism: "Diseases have had their day."

Disease, of course, is always with us, and, if we wish to systematise our experience, some plan of classification must be adopted. And so we are beginning, almost insensibly, to go back to the scheme of diagnosis adopted by the Empirical School of Alexandria in the third century before Christ and, first recognising kinds of symptom-groups or *syndromes*, then proceeding to find out *why* in particular cases this or that rather than any other syndrome is manifested, without bothering about formal diagnosis by way of identification with a text-book type, like postage stamps from a catalogue. This, it seems to me, is the way of true diagnosis; in Galen's phrase, the thorough understanding of things present.

Now, it is precisely in the course of the attempt to make in this way an individual diagnosis—one, that is, not merely conventional or classificatory—that we come to appreciate the second tendency of which I have spoken. It is usual in making an individual diagnosis to attempt to assess in the first place whatever organic basis there may be for illness, and in the second place, what I will call the neuro-humoral element. But this is not enough. Diagnosis is not completed when we have summed up the clinical findings in terms of organic, bacteriological, humoral, or reflex pathology and ætiology, if we have not taken account of the patient's psychological history and make-up, and of the extent to which the clinical manifestations themselves may be psychogenic. I do not mean by this, to the mere extent that they may be fanciful, but to the full extent that humoral states and functional, if not organic manifestations, may be as truly psychogenic as are the tears we shed when we are sad, or as used to be the diarrhœa that afflicted some men in France at zero hour.

Individual Psychology of Adler.

We are, in fact, coming to see that we can never rightfully regard an individual as necessarily either an "organic" case or a "functional" one. The patient is always an individual, and all aspects of his individuality must always be considered. In this sense, then, every case is at once one of organic, of neuro-humoral, and of psychological importance. For this reason, I suggest to you that, of all the conflicting schools of psychology now in vogue, none has such claims on your attention as the Individual Psychology, founded by Alfred Adler, and developed by such of his pupils as Wexberg, Seif, Weinmann, and others. I will say something presently of the attitude adopted by physicians who are Individual Psychologists towards the mind-body problem, but I want now to emphasise that, as a result of the study of *syndromes* rather than *diseases*, and of our gradual realisation that syndromes are the ways in which kinds of individuals react, in kinds of circumstances, to kinds of stimuli, we are beginning to form mental images of *types* of *individuals*. Now, though we must only admit these *types* as fictions, or fictive ideals, and never as real existences, their recognition is useful and takes us back to the doctrine which distinguished the sanguine, the lymphatic, the pituitous, the bilious, and the atrabilious temperaments, as severally depending upon predominance of one or other of the corresponding humours. This typification in terms of temperaments had for its basis that firm belief in the *humoral* ætiology of Disease in which we still show confidence when we speak of toxins and of endocrine-gland balances. But humoralism as a doctrine of constitution is only a partial expression of the truth and although from time to time countervailing efforts were made to typify in terms of morphology or of *form* not much advance was made until, at the beginning of the Nineteenth Century, the *organicist* theory of Disease as dependent upon structural change came into fashion. Since then there have been many attempts to classify temperaments, or constitutions upon a morphological or anatomical basis.

In Table A (adapted from one drawn up by my friend, Dr. MacAuliffe of Paris) we have a conspectus of various schemes that have been put forward during the last 150 years, and I draw particular attention to the repetition in different forms of the very natural, straightforward, and convincing division into respiratory, muscular, digestive, and cerebral types, each characterised by predominance or superiority of one set of functionally associated organs. The cerebral type represents, of course, *homo sapiens;* the man whose adequate respiratory, muscular, and digestive symptoms are controlled by intelligence.

Sigaud's Classification.

This scheme, first put forward by Hallé, was given importance by Sigaud, a French provincial physician whose genius was unrecognised during his life-time, but who has given us the best definition of *disease* yet achieved. This definition (modified very slightly in translation) declares disease to be the dissociation of the functional unity of the individual. Sigaud's classification, then (as we may call it), is something more than morphological; in relating organ-form with functional capacity it accords with Sigaud's definition of disease. Now, when in any individual one system (such as the digestive) is dominant, another system (perhaps the respiratory) must be at least relatively inferior. In this case the inferior organ or system will be, as we say, susceptible; a *locus resistentiæ minoris*. Such an organ or system may break down, and become (as we say) the seat of disease. On the other hand, if the individual meets the inferiority with prudence and courage, development and compensation, of even a very high degree, may ensue. Sometimes, as it were, a middle course of compromise or neurosis is chosen and the patient manifests what is called *functional* disease in connexion with the inferior organ or system. But if a robustly organised system or organ, or functional capacity, is allowed to dominate the individuality, to strike the keynote of the style of life, the resultant lack of balance may itself become a factor in disease of the dominant system or function. Thus, while the child with the weak organ-system may, if encouraged, grow out of his weakness, or at any rate make the best of it, the man with a strong bellows may become emphysematous and bronchitic in later life; the athlete with the strong heart the subject of cardiovascular disease; and he with a sound belly the possessor of a huge liver, a fatty omentum, and an enormous colon. In the same way it is not the sexual weakling, but the sexual athlete, who becomes the impotent victim of locomotor ataxy.

This point of view—one of extreme importance—is given in Adler's doctrine of organ-inferiority which lies at the foundation of Individual Psychology.

But the Table which MacAuliffe has drawn up does not, as a matter of fact, show the correspondence between Sigaud's classification and his own notion of a division of human beings into *flat* or *dry* and *round* or *wet* colloidal types. This, which again combines humoral and morphological type-criteria, has been extended to the animal kingdom, and Wheeler in America has charmingly illustrated the point by drawing our attention to the contrasting species of insect, plump and round on the one hand, and slimly elegant on the other, belonging to the same genus.

Now, although the synthetic recognition of the functional biochemical, or humoral, and morphological, structural, or organic considerations of personality types in itself marks a great advance on more restricted conceptions, nevertheless, so far, we have no hint of the value of psychological correlations.

Nevertheless, in the work of Kretschmer, this element is admitted, and we are bound to find with him that there is on the one hand a definite alliance in many cases between the asthenic physical character and the schizoid mental style (which in disease passes into dementia præcox or schizophrenia), while on the other hand, the pyknic physical style seems the counterpart of the cyclic mental type which, in dissolution, passes into cyclothymia or manic-depressive insanity.

Now Kretschmer's asthenic schizoid is none other than the *type plat* of MacAuliffe, while his pyknic is as clearly MacAuliffe's succulent, blubbery, *type rond*. These two types, the flat schizoid and the round pyknic, have been fixed for all time in Don Quixote and Sancho Panza. The same antithesis is seen between Rodin's John the Baptist and a fat-bellied Chinese philosopher in Ming porcelain. Jung's introverts are on the whole of the former, and his extraverts of the latter type.

But carrying comparison a little further, it is very interesting to put in parallel, on the one hand the respiratory, the muscular, and the digestive types of Sigaud, and on the other three racial types: the lean Aryan, the muscular Negro, and the plump Mongol. I call the attention of veterinarians to the curious correspondence between Sigaud's first three types and the stock-breeder's classification of cattle into "asthenic" *milkers*, muscular *workers*, and bloated *feeders*.

Going still further afield, whatever orthodox anthropologists may say, there is a definite parallelism between the respiratory and racial Aryan and the chimpanzee (or gibbon); between the muscular negro and the gorilla; and between the digestive (or pyknic) Mongol and the orang-utan. The bearings of this observation, in Jack Bunsby's words, lies in the application of it. But the *truth* of the observation (which extends even to resemblances in posture) is now widely recognised, especially in Germany. This, however, is not all. Just as dementia præcox reveals the schizoid type in a sort of chimpanzoid regression, so we find some idiots of a brutal muscular "gorilloid" type that Langdon Down called Ethiopian, while the imbecile mongoloid is, as it were, an orangoid caricature of the pyknic and the racial Mongol. In a capital picture of a nude Japanese girl by Stratz, we note that her round figure form displays the very characters which, in the imbecile mongoloids amongst us, are wrongly taken to be "pathological."

Certainly one lesson seems gradually to emerge from comparative observations of this nature, and that is that racial types are not confined to geographical or political boundaries. We have in England mongoloids of high and of low grades; negroid types are found in China; Jewish in Burma; and so-called Caucasian in Central Africa.

Bearing upon Man's Origin.

What bearing these and other facts will ultimately be held to have upon theories of Man's origin it is impossible to say, but, if we adopt the Darwinian premises, we come, in their light, to hold views concerning the descent of Man which are quite irreconcilable with the mono-phyletic hypothesis of orthodox Darwinism. It may be that the poly-phyletic hypotheses of Klaatsch, Arldt, Sera, Frasetto, and others will be found satisfactory in part, at any rate. But recently interest has been aroused in France by the new theory of *Ologenism* expounded by Montandon, derived from the *Ologenesis* of Rosa. Ologenism suggests the simultaneous appearance in many different centres of anthropoid creatures, each branch or phylum dividing into two subordinate phyla, the one coming to early maturity, the other with retarded development. In this way Montandon explains how it is that the curious resemblances and differences and cross resemblances and differences between the geographical and political and anthropological groupings that we call *races* have come about. But the interest of this to us is that Montandon refuses to assert that there is any *necessary* correlation between physical type and cultural style. Here we come into touch with Individual Psychology, which insists that, although as observers we must recognise frequent mind-body correlations, we must not fall into the error of assuming the psychological style to be inevitably fixed by the physical character. I have said that an organ inferiority may terminate in either disease or in strength, while conversely an organ superiority may become a source of weakness. In a word, the individual (within limits, it is true, but within wide ones) has the *choice* of response to his somatic organisation. Individual Psychology emphasises a tremendous clinical truth in denying that our psychological style is necessarily dependent upon our physical make-up or our endocrine balance, in the way that certain writers pretend. It is nothing of the sort. We have deaf musicians like Beethoven, stammering orators like Demosthenes, myopic painters, and charming actresses whose facial handicaps are obvious. There are men who look like eunuchs and are not; athletes who would be thought virile and are impotent or homosexual. We know women who are beautifully feminine in face and figure and nevertheless without an iota of sexual or maternal feeling, while others, as we say, masculine in appearance, are most womanly at heart. In the same way, whilst many women feel themselves unsexed after ovariotomy or hysterectomy, as every gynæcologist knows, many who have been thus operated upon seem to be released from sexual inhibitions with the disappearance of the fear of pregnancy. Many women and not a few men whose thyroid glands make

obvious default escape treatment because they are mentally alert; and there are undoubted cretinoids and achondroplastics in both Houses of the Legislature. The fact is that, often enough, a physical shortcoming is made the excuse for a mental attitude which might otherwise be an incentive to the effort that *compensates* and *overcomes*. I do not say that there is *no* physical defect that cannot be overcome, but we may agree with Adler that it is certainly better to teach *as if* there be none. Ready acquiescence in the fatalistic doctrine of psychical determination by physical conditions is not only in opposition to unbiased clinical observation but leads to despair. The Darwinian philosophy of evolution by way of congenital variation, natural selection, and the survival of the fittest, is that of the pessimistic frog in the milk can, whilst the teaching of Lamarck (with which Individual Psychology has so much in common) is that of the optimistic batrachian in the same predicament who went on swimming and found himself ultimately on a pat of butter. If, then, it is true that there are certain correlations between physical type and psychological style, it is no less true that the individual has the choice between several possible reactions to the same stimulus, trauma, or defect.

Medicine the Study of (Maladjusted) Man.

Two lessons of real importance seem to emerge for our consideration. Medicine must be recognised to be, not the study of the false entities we call diseases, but a branch of anthropology—the study of Man. But it is a branch of anthropology which has to do with maladjusted man. We then find that, while it is useful to study types of mind and body, as we have been doing to-night, our real task in diagnosis is to comprehend the individuality of our patients, comprehensively recognising not merely their morphological types or states, and not merely their functional and neurohumoral values, but their psychological histories and life styles as well. In this way Medicine becomes much more than an affair of the dead house, the laboratory, or even the farmyard, and a matter of human interest.

If we get into the habit of reckoning the psychological values when making individual diagnoses, we shall be surprised to find how far we are led, even when dealing with what we call the specific infections but are better considered as individual responses to certain conditions! Thus, even phthisis turns out to have its origin, not in an unprovoked or casual assault by the bacillus but in the *discouragement* of the individual that slows and shallows his breathing and, as we say, lowers his vitality. Secondly, to adapt some famous words of Adler's, what matters is not so much the physical constitution or the environmental stage as the courage with which the difficulty is met. Indeed, there is no doubt that, though the Ethiopian may not change his skin nor the leopard his spots, those who behave in certain ways tend to change physically, in accord. Our endocrine balances are at least as, if not more, freely controlled by ourselves than are we by them. The psychical element is the *Primum Mobile* to which the "somatic resonance" is secondary. The physical is but the stalactite deposit left by the dripping water that, in dripping, may either form or wear away another stone. The *ultimate* physical make-up, indeed, of ourselves and the *primary* physical make-up of our children may be even far more than we think the consequence of our own decisions, and there is profound significance in the words of Jeremiah: "The fathers have eaten a sour grape and the children's teeth are set on edge."

NEWLY IMPORTED PARROTS.

WRITING in the *Manchester Guardian* of March 1st the Marquess of Tavistock says that the recent outbreak of psittacosis appears to have been entirely confined to Amazon parrots. "For the guidance of inexperienced persons," he says, "I might add that the indications of an established bird are fully grown and unworn wing and tail feathers; and of a healthy bird, bathing, stretching, talking, screaming when not alarmed, and displaying by spreading the tail and contracting the pupil of the eye. The signs of a newly imported Amazon are worn, broken, or clipped wing and tail feathers; and of a sick one, silence, including complete abstention from talking, dirty and ruffled plumage, watery droppings, and a habit of sleeping with the head 'under the wing' and both feet (not one foot) on the perch.'

CONSUMPTION OF "RED BIDDY" IN SCOTLAND.

To the Editor of THE LANCET.

SIR,—Readers of THE LANCET (March 1st, p. 494) may have been somewhat "intrigued" by the question addressed to the Secretary of State for Scotland on the 25th of the past month as to the nature and use of an intoxicating drink known as "Red Biddy." In that wonderful "Enquire within," Martindale's Extra Pharmacopœia (19th edition, vol. ii., p. 26) is to be found R. E. Corder's account of it as given by him in the *Daily Mail* as follows:—

> "In Glasgow the bars close at 12 noon on Saturdays so that the shipyard worker may take home his wages, but they reopen at 5. The drinking dens are crowded. The popular tipple is '*Biddie*,' a deadly mixture of wine and methylated spirit. The red wine is bought at the less reputable bars at ninepence a quart bottle; and the methylated spirit, or 'feck,' as it is known here, is brought in and mixed with the so-called wine. The result is precisely the same as that seen in the New York drunkard. 'Red Biddie' is a devil's brew from a witch's cauldron. It makes the toper not so much drunk as doped. Glasgow police officers state that a man or a woman taken under the influence of 'Red Biddie' might be unconscious for 24 hours, and at the end of that period, if they take a drink of water or any other liquid, they immediately become drunk again. They are like subjects under a hypnotic trance. In whatever position their limbs are placed, so they remain."

Whether this interesting liquor is to be described as "*devil's brew*" *or as* "*wonderful value*" *depends entirely* on the point of view.

I am, Sir, yours faithfully,
London, March 3rd, 1930. JAMES DUNDAS-GRANT.

ELSIE INGLIS MEMORIAL HOSPITAL.

IN formally opening the Elsie Inglis Memorial Hospital, of which an account was given in our columns two years ago (THE LANCET, 1928, i., 730), Mr. Adamson, Secretary of State for Scotland, said that the Queen looked forward to paying it a visit on the first convenient opportunity. The hospital, which is within stone's throw of the Palace of Holyroodhouse (to give it the official title) is yet in the heart of a crowded quarter and the calls on it demonstrate the soundness of the managerial policy in placing it there. The outlook on the King's Park and Arthur Seat is superb.

At the opening the speakers included Dr. Maud Chadburn, of London, and Dr. Margaret Fairlie, Dundee, and in the evening there was a memorial dinner of 120 women, of whom 60 were medical.

"The Hospital," writes our Edinburgh correspondent, "grew out of the Hospice in the High-street. This was established on the initiative of Dr. Elsie Inglis long before the war and its success was phenomenal. But the Hospice, so long as it was used, and the new Hospital, have always been 'run by women for women.' This is the culmination of the long fight begun by Dr. Jex-Blake to secure for women a place in the Edinburgh profession; her own material memorial is the Women's Hospital at Bruntsfield."

SORE TONGUE.

A CORRESPONDENT would be glad to hear of treatment for recurrent attacks of sore tongue, commencing suddenly with enlargement of papillæ, and followed by minute ulcers on sides. There is no other inflammation in the mouth. and radiograms of the teeth are negative. A test-meal shows free hydrochloric acid. The attacks last about a week and intervals are variable.

SO-CALLED BIRTH-CONTROL CLINICS.

UNDER this title Dr. Marie Stopes sends us for publication the following warning, due to the iniquitous use of her name by a convict who recently received five years' penal servitude in connexion with the sale of abortionist remedies:—

"May I therefore emphatically warn everyone in the country that *no* pills, remedies, or anything of *any* commercial nature has any right whatever to the use of my name. I have *never* been associated even remotely with any such and condemn them utterly."

PARKING OF DOCTORS' CARS.—The Traffic Committee of the Cape Town Corporation reports that it has received a deputation from the Medical Association of South Africa, which submitted that practitioners should be allowed to park their cars in reserved areas close to consulting rooms, or alternatively that their cars, licensed as such and bearing a special badge, should be allowed to have kerbing and parking privileges one-third to one-half in excess of that of the ordinary. The committee replied that if special parking facilities in public streets were to be provided for any particular profession, claims would immediately be made by others for similar facilities. It refused the application.

ABSTRACT OF THE

Hastings Lecture

ENTITLED

HEALTH AND EMPIRE.

Delivered at the British Medical Association House on March 12th, 1930,

BY SIR ANDREW BALFOUR, K.C.M.G., C.B.,

DIRECTOR OF THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

[Sir Andrew Balfour, taking for his opening text the phrase "Bora afia," which means in the Swahili tongue "Health is the chief thing," commenced with a moving description of the risks and hardships of those who founded the British Empire by their enterprise and endurance, continuing :—]

If, in that great struggle for domination, too much account had been taken of sickness and pestilence, it is conceivable that the goal would never have been attained. Still, there is a great difference between a reasonable care of health and a reckless squandering of life, and time and again the latter was in evidence, and such knowledge as had been gained by bitter experience was cast into the melting-pot. Lest we forget, and with the view of contrasting the conditions which prevailed during the period of foundation and expansion with those obtaining to-day, it seems desirable to glance briefly at some of those perils to health which our forbears had to face. In doing so we can but wonder at the courage and tenacity which enabled the pioneers of Empire to triumph over disease and death, the while we deplore the needless loss of life, the lack of lore, and the short-sightedness which brought thousands upon thousands to an untimely end.

Let it be remembered that, until comparatively recently, the heart of the Empire itself was far from sound. In the spacious days of the Virgin Queen those who fared foreign encountered diseases with which they were quite familiar at home, though it is true they often encountered them in more terrifying guise than that to which they were accustomed. Unable to cope with them in the motherland, they were still less able to deal with them abroad and this, in certain directions, remained true until last century had run much of its course. England was scourged by cholera as late as 1866, and in 1869 relapsing fever was claiming victims in the poorer parts of London. In 1863 malaria formed the subject of inquiry, for it still persisted to a considerable extent in the fen lands and the marshes. One disease, not often seen ashore, but which dogged the mariner and the gentleman adventurer afloat was the sea scurvy which, until the addition of lemon-juice to the sailor's ration, played havoc with the personnel of the Navy and the mercantile marine. This was in the old days of sailing ships and long voyages, and before a simple and single remedy magically controlled it. Yet, although Hawkins saved his crews with lemon-juice in the Azores in 1590, it was not until 1844 that it was made a compulsory issue in the British Navy, despite all the efforts of the great naval hygienist, James Lind, in the preceding century and those of his disciples and fellow countrymen, Trotter and Blane.

THE PRICE OF WAR.

It is also worth noting, as showing how Empire building may favour the ravages of disease, at least when war is the trowel, that there were no less than 10,000 cases of scurvy amongst our Indian troops in Mesopotamia during the last campaign. Truly "Disease and Empire" would be a better title for this discourse than that which it bears. That such is indeed the case is shown by various happenings throughout the seventeenth and eighteenth centuries. It is, of course, impossible to deal with these in detail, but a few examples may be culled at hazard which indicate how correct was Lind, at least with respect to the Navy, when, in the Advertisement to his remarkable essay on the preservation of the health of seamen, he wrote: "For the number of seamen in time of war, who die by shipwreck, capture, famine, fire or sword, are but inconsiderable in respect of such as are *destroyed* by the ship diseases, and by the usual maladies of intemperate climates."

[The lecturer then referred his hearers to the pages of Roderick Random and to Smollett's account of the destruction wrought among ship's companies by yellow fever. Other pertinent references were to the account written by Charles Curtis, a naval surgeon, of the "Diseases of India as they appeared in the English Fleet and Naval Hospital at Madras in 1782 and 1783"; to Shield's graphic description of the Batavian epidemic of 1800; and to the letters of a certain Dr. Pinckard, physician to the Bloomsbury Dispensary, whose letters, sent home when serving with Sir Ralph Abercromby's expedition at the close of the eighteenth century, were published in 1806. Passing from the disasters due to diseases among the fleets and armies, Sir Andrew Balfour told briefly the story of the ill-fated Darien scheme, where disease proved as fatal as it did 200 years later, in almost the same spot, when attacking the original constructors of the Isthmus of Panama. He continued :—]

It must also be remembered that if, in the olden days, the Empire paid scant heed to the health of its white populations it paid even less to that of the native races which passed under its sway, except here and there in the case of slaves which possessed monetary value. Now, however, it has shouldered the white man's burden and throughout its length and breadth the care of the health of native communities is a feature of modern administration. What this means is not always fully realised. I have said elsewhere that a skilled and sympathetic doctor is more of a civilising and pacifying force than a company of infantry, and a well-run hospital has greater power in the long run than a battery of maxim guns. Some may be disposed to think this statement an exaggeration, and yet what do we find? The latest medical report from Fiji contains a chapter by Dr. J. M. Lambert on the work of the Western Pacific Health Service, in the course of which he says:

> "There is a certain amount of grim romance about our work in the Solomons. In October, 1927, on the savage island of Malaita, the District Officer, his white assistants, and numbers of native police were killed on a tax-collecting tour. A very few years ago, the answer to that might have been the punitive visit of a war vessel, a shelling of the district and indiscriminate killing of natives. On this occasion there was a painstaking arrest and a fair trial of accused participants. Within three months, also, the Government had two yaws and hookworm units at work on this island. The work has been continued there for the year except for a week or so, when they were transferred to another island because a rumour, which proved without foundation, said they were to be lured back into the hills and massacred. Immediately after they left, Malaita native delegations began to approach Government for their return, showing that only a few months of the work had given them an appreciation of the benefits received."

The change for the better began in this country, though there were not lacking powerful influences abroad and more especially in India which, under British rule, has, in certain respects, always been a remarkable centre of medical and hygienic activity. Yet it was the new outlook in England about the middle of last century, an outlook which resulted from the enthusiasm and the unremitting labours of Edwin Chadwick and his disciples, which laid the foundation of all that followed. The pioneers of sanitary reform preached the gospel of cleanliness and that comparatively simple evangel accomplished great things both at home and abroad. The gospel might be a simple matter, but its acceptance by those in high places and by the populace was very much the reverse, even when repeated cholera outbreaks came to the assistance of the reformers, and it needed the most dogged determination to effect a sanitary revolution. A lesser man than Chadwick would have given up in despair but, aided by Southwood Smith, Simon, and others of like kidney, he would not acknowledge defeat and well earned this fine tribute paid him in 1890 by another of his followers, Sir Benjamin Ward Richardson:

> "For so much labour on behalf of the health of this nation, and of all nations which profit by English industry, few public men of this century have received fewer public rewards or favours than this man who, born with the century, stands probably at the present moment of it, when compared with others of the same term of years, absolutely alone in the possession of ability, enthusiasm and genius. Happily no reward, no thanks can surpass those which have come so richly and so silently in the results he has lived to see as the fruits of his labours: *the foundation of a new* life-saving science; the gratitude of the best and wisest of mankind; the acknowledged baptism of an imperishable name."

What Chadwick and the other pioneers did was to place sanitation upon a sound basis, to invoke the majesty of the law on its behalf, and to make obedience to the laws of health an integral part of the life of the people. Naturally, when the efficacy of public health work had become established in Great Britain, those possessions which now constitute the great Dominions were not long in following the lead of the Motherland and putting their respective houses in order.

On the whole the problems to be met and mastered in Canada and New Zealand resembled very closely those which this country had to face in its efforts to secure sanitary salvation, but South Africa and Australia had special troubles of their own. Thus, from 1889 onwards South Africa had to cope with plague and, of late years, its plague problem has assumed special features and has presented peculiar difficulties owing to the infection of the veldt rodents. In Australia, and also in New Zealand, the prevalence of hydatid disease, due to a parasitic worm, has introduced questions and measures which are unfamiliar in the old country; plague in Australia was at one time a cause of trouble and expense; while the fact that a considerable part of the Australian continent is within the tropic zone has necessitated attention being paid to the matter of acclimatisation and to the prevention and cure of ankylostomiasis. In both South Africa and Australia the leper problem had to be faced, so that in both these Dominions conditions were somewhat specialised.

It is, however, only when we turn to India and the Colonies, for the latter are nearly all tropical, that there is impressed upon us the fact that, until science had led the way, the physician was terribly handicapped in his efforts to cure disease, while the hygienist was also hampered and perplexed, although it is true that, by following the lines indicated by the pioneers and adopting cleanliness as his slogan, he was able to accomplish much in the way of prevention and amelioration. It was not always necessary to wait until sundry parasites had been discovered, certain vectors of disease identified, some life-cycles of lowly organisms worked out before remedying the conditions.

To do this country justice, she usually cleaned up places on which she laid her claws, at least after she had learned to keep herself clean, or, in view of present conditions, should we say fairly clean?

THE DAWN OF TROPICAL MEDICINE.

Yet, viewing the situation broadly, it may with truth be said that it was not until the new era of tropical medicine dawned, with its surprising revelations and its vistas of hope and of health, that any remarkable progress was made either from the purely medical or from the purely sanitary standpoint. Perhaps the most outstanding example of results following upon the heels of research is to be found in what occurred at Malta. The organism of undulant or, as it used to be called, Malta or Mediterranean Fever, had been discovered by Sir David Bruce in 1888, but it was not until 1905–06 that a Commission of the Royal Society investigated the problem of a malady which was a veritable curse, for, though it did not kill many sailors and soldiers, it kept large numbers of them in hospital and led to prolonged disability. The loss in personnel and in money was indeed very serious. The labours of the Commission, following the lead given by Dr. Zammit, of the Malta Board of Health, who was himself appointed a member of the Commission, conclusively proved that the path of infection lay through the goat. In other words, the milk of infected goats transmitted the disease to man. Precautionary measures were at once taken, and within a year the disease had been practically eradicated from the Navy and Army.

Let it be clearly understood, however, that we must not attribute all the advance of recent years to discoveries like those of Theobald Smith on Texas Fever, Bruce on undulant fever and trypanosomiasis, Manson on filariasis, Ross on malaria, and so forth. Other factors were at work, such as the realisation of the value of the tropics as a source of raw material for the Empire, improved transport both by sea and land, improvement in the diffusion of information, greater interest in native races, the strategic importance of certain places from a military and naval standpoint, better food conditions, more comfort and a lessened consumption of alcohol. In short, the tropics in one sense became the fashion. European nations and even the United States scrambled for them and, as vested interests developed, so did the necessity of spending money and of educating the indigenous populations.

INDIA AND AFRICA.

Under such circumstances it is clear that India could no longer tolerate conditions like those which obtained in former times when, as Dr. Busted tells us, the white citizens of Calcutta were wont to meet after the rains under the great Banyan tree in the Maidan and congratulate themselves that they were still alive. As a matter of fact, India had already passed far beyond this stage for, as has been stated, she had been well served by medical officers and research workers, both in the Indian Medical Service and the Army Medical Service, and had benefited especially from the light thrown upon the method of spread of cholera by John Snow in London, von Pettenkofer in Munich, Bidie, Parkes, Duncan, and others in India, as well as by Koch's discovery of the cholera vibrio, the cause of the disease. Moreover, in the case of the large European cities money had not been lacking even for those Cinderellas of municipal expenditure, sanitary improvements, so that by the time research began to clear up some of the more important mysteries in tropical pathology, India was on rather a different footing from the other parts of the Empire. Whether she made the best use of her advantages in this respect is quite another question, but it must always be remembered that in India health problems are on a vast scale and that the difficulties are enormous.

Under the process of settlement and expansion the dreaded West Coast of Africa could no longer remain the white man's grave, as it had with justice been called throughout the eighteenth and much of the nineteenth century. No longer was it conceivable that the average tenure of office for Government officials should be less than 12 months. No longer was there any need for a judge to devise the ingenious expedient of making his home on a small vessel moored off the coast and going ashore only to carry out his official duties. No longer could the gravestones in the cemeteries and the memorials in churches be permitted to exhibit record after record of unfortunate persons who had perished under the age of 40. Civilisation altered the situation, and it is worth noting that the British Empire as a civilising and colonising Power has been a good ally to health. At least, we may say that the balance is on the right side for, of course, this very process of trade expansion and settlement has resulted in terrible tragedies. Diseases have been introduced which have decimated native populations. Think of the malign influence of the slave trade in which Great Britain for so long participated, the horrible state of the slave ships in which, too often, dysentery and ophthalmia were rife, the probability that yellow fever was introduced into the New World by this iniquitous traffic. Still, when all is said and done, imperial development has, on the whole, brought about hygienic improvement, and incidentally I may say that, personally, I believe this process of "bonification," as the Italians call it, will prove the main factor in conquering such diseases as malaria and African sleeping sickness. Yet those researches to which allusion has been made, or at least some of them, had an influence apart from their intrinsic value. Once the rôle of the mosquito as the vector of the parasite of malaria had been demonstrated and the truth of Manson's malaria-mosquito hypothesis established by the labours of Ross, a wave of intense interest and of hopefulness passed over most of those associated with the tropics, though, as ever, scoffers were not lacking. There was something romantic about the idea, and the discovery seemed to hold out vast possibilities. Attention was thereby drawn to tropical latitudes and, in fact, the very controversy which arose proved beneficial. A similar and even greater outburst of enthusiasm, at least in certain circles, followed the American proof that the virus of the dreaded yellow fever was mosquito-borne, and the demonstration by Gorgas in Havana that the new knowledge had placed in our hands effective methods of prevention and control. Much the same stimulation resulted from the finding that the tsetse-fly—known to the British public from the writings of David Livingstone, was responsible for the spread of that negro lethargy or sleeping sickness, the nature of which had been for so long a time enveloped in mystery, and which had wrought such havoc on the shores of the Victoria Nyanza.

It was clear that at last we were getting to grips with those tropical maladies which had been one of the chief factors preventing the opening up of Africa and the exploiting of other regions, some of vast potential wealth, within the torrid zone.

[The lecturer then considered the home land in its imperial relationships, and pointed to the ignorance of the public, as a whole, as to the system of information whereby the Ministry of Health and the Colonial Office are notified about infected ports. He recalled the difficulties due to the country not being self-supporting in the matter of food, and finally referred to the lack of education of the public in respect of health problems. After referring to the incidence of dysentery, small-pox, and other scourges, as well as tuberculosis, malaria, and venereal disease, he closed his address with the following testimony to the value of education in hygiene and tropical medicine:]

Education in Hygiene and Tropical Medicine.

Turning now to the education of those specially charged with the preservation and restoration of health, there is a movement afoot to permeate the medical curriculum, as Sir George Newman puts it, with the preventive idea. It has made greater progress in the United States than in this country, but let us hope it will not be abandoned, for it is a sound conception, difficult of execution no doubt, but withal essential, if the doctor of the future is to be a trusted and valued ally in health campaigns. The establishment of the London School of Hygiene and Tropical Medicine marked the commencement of a new era in post-graduate public health education in this country and it has also an imperial aspect, the full significance of which will only be apparent as the years pass and more and more of those trained on new and approved principles take their places in the fighting line both in this country and overseas.

To Manson we owe the idea of special schools in England for training the medical man and woman in the control and care of diseases of the tropics or ever he or she fares foreign. London and Liverpool have done much in this direction in the past and the University of Edinburgh, always a pioneer in matters of medical education, has recently reorganised and extended its courses of instruction in tropical medicine and hygiene. An important development in connexion with the London School is the institution of courses in tropical hygiene for laymen and laywomen. Those who attend them will not enter upon tropical life unprepared and will exemplify the truth of the saying, "forewarned is forearmed."

The value of the graphic museum as a means of demonstrating all that "Health and Empire" connotes has been recognised at the London School and also at the Wellcome Bureau of Scientific Research, while it is gratifying to note that museums of this kind are springing up here and there in the Colonies where, properly conducted, they cannot fail to assist the great cause.

Hospitals for tropical diseases, like that of the Seamen's Hospital Society, play an honourable part, not only by helping the sick, amongst them many servants of the Empire, but by providing clinical material for teaching purposes and by quickening the interest of many in the welfare of our tropical possessions.

Despite the influx of medical men and women into our tropical possessions the old cry still holds good, "What are they amongst so many?" and hence we view with sympathy the extension to Africa of a system of medical training for the native which has proved its value in Ceylon, Singapore, and Fiji. This, again, is imperial work and cannot fail of its effect if only it be carefully and faithfully prosecuted, as would appear to be the case in Khartoum, where good progress is reported.

Lastly, mention should be made of the useful and widespread activities of the Royal Sanitary Institute, both at home and abroad, in the way of training and examining those desirous of becoming sanitary inspectors and thus constituting themselves links, and very valuable links, between the medical officer of health and the population for whose welfare he is responsible.

Research.

And now as to research, that much abused word and yet that weapon which, wisely wielded, has opened up and can open up for us paths in the jungle of ignorance, dispelling darkness and gloom and revealing vistas of hope and cheerfulness which, in their turn, conjure up visions of health and longevity.

In Great Britain there are many centres of research, but I will refer only to the ceaseless and ever-increasing investigations of the Medical Research Council, which have already resulted in discoveries, some of which are of vital importance to the health of the Empire. It is surely a fascinating thought, as Sir Walter Fletcher has said, that at any moment some piece of work in the laboratory or in the field in this country may profoundly influence communities existing under totally different conditions thousands of miles away. Yet it is true, and so is the converse, for research is proceeding in many parts of the British Empire. Moreover, serious efforts are being made to coördinate it. India was somewhat of a pioneer in this matter so far as research work within her own vast territory is concerned, and now the report of the Fletcher Commission has indicated further and, presumably, better lines of development. To help research in the Colonies a special Colonial Medical Research Committee has been established and is beginning to make itself felt.

Indeed, in every direction we can chronicle activity, if not marked progress, but it is necessary to sound a note of warning. Research has outstripped practice. We are not applying properly much of the knowledge we of the cerebro-spinal fluid is of the utmost importance in the investigation of the problem of the ætiology of disseminated sclerosis. Observations on the cerebro-spinal fluid were the starting-point of the investigations which form the basis of this present research on disseminated sclerosis. In 1926 I carried out research to investigate the causation of the colloidal gold reaction in cerebro-spinal fluid from patients suffering from various diseases. It was found that in the case of disseminated sclerosis the cerebro-spinal fluid may appear normal according to the usual laboratory tests, but more often it shows two pathological changes, occurring either independently or together—namely, a positive globulin reaction in about 40 per cent., and a positive gold-curve in approximately 77 per cent. of cases. The colloidal gold test, therefore, assumes particular significance in disseminated sclerosis, since it is often the only abnormality demonstrable in the routine examination of the cerebro-spinal fluid, and it seemed probable that if the causation of this reaction were determined, valuable information would be obtained as regards the ætiology of the disease.

Experimental Investigations.

The gold test has been carried out in 189 cases of disseminated sclerosis. Seventy-seven per cent. of these gave positive gold-curves, specific curves being obtained, characterised by colour changes within certain dilution zones.

The colloidal gold was prepared by the following method: To a boiling solution, consisting of 100 c.cm. of distilled water and 1 c.cm. of a 1 per cent. solution of gold chloride, are added 9 drops of a 2·5 per cent. solution of formalin. Fifteen seconds later, 15 drops of a 2 per cent. solution of potassium carbonate are added. If necessary, a further 1 to 3 drops of the latter solution are added after an interval of 15 seconds. Not more than 18 drops altogether are added, and the solution must be kept boiling all the time. The colour change must be instantaneous. Five c.cm. of this solution should be completely precipitated in one hour by 1·7 c.cm. of a 1 per cent. solution of sodium chloride. The gold solutions used were titrated by using sodium chloride as a precipitant, according to the method described by Novick.[16] Such accurately standardised gold only was employed. Colloidal gold solutions should not be used for 12 to 24 hours after being prepared, but should not be more than seven to ten days old, since the reaction after this period becomes more alkaline, and the gold consequently less active.

The various precautions necessary in the preparation of colloidal gold solutions and the actual test are described in numerous papers on the subject, and need not be discussed in this preliminary communication. It is only necessary to point out that dilutions of cerebro-spinal fluid varying from 1/10 c.cm. to $1/10 \times \frac{1}{2^{(n-1)}}$ c.cm. in an *n* series of tubes, were employed in the experiments described in this paper. The final reading should be taken 12 to 18 hours after performing the test, but frequent observations of the tubes are necessary to ascertain in which tube precipitation first occurs. The results showed that in disseminated sclerosis there is one important diagnostic point about the gold-curve revealed by such observation of the tubes—namely, that precipitation almost invariably occurs first in the fourth tube, that is, in the dilution 1/80. Whatever the final reading, this change can usually be observed within an hour of doing the test, although at first the precipitation may be very slight.

It was found that in 70 per cent. of these cases giving a positive gold-curve precipitation occurred in the dilutions 1/80 to 1/640, producing a curve of the type 00032222000. Initial and usually maximal precipitation was manifest in the 1/80 dilution. In certain stages of the disease the cerebro-spinal fluid gives a type of curve in which precipitation occurs in the first five or six tubes. In either case the degree of precipitation is usually not greater than that indicated by the figures 3 or 4. Complete precipitation is rarely seen. The type of reaction (*Verschiebung nach oben* or *Rechtsverschiebung*) in which precipitation occurs in the last two or three tubes, has been observed in two only out of the 189 cases. This reaction is usually ascribed to the protective effect of excess of albumin, but clearly this could not be the explanation in these cases, since the amount of albumin was normal.

The particular significance which the gold reaction assumes in disseminated sclerosis and its relation to other important changes in the cerebro-spinal fluid in this disease are discussed later in this paper.

It has been suggested by some observers that the gold reaction is due to the products of degeneration of nervous tissues, and is related to the result, rather than the cause, of the disease. Such a theory ignores the specificity which characterises the form of the gold-curve in various nervous diseases. These experiments showed that the gold reaction is characteristically positive in early cases before structural changes are present, also during so-called remissions, when presumably the morbid process is stationary so far as the nervous system is concerned. The gold reaction is, therefore, probably related to the cause rather than the effect of the disease, though the latter may be responsible, directly or indirectly, for a positive globulin reaction.

Although many theories have been advanced on the subject, the nature of the colloidal gold reaction in the cerebro-spinal fluid is at present unknown. The test is based on the work of Zsigmondy,[17] who showed that precipitation of colloidal gold by electrolytes could be prevented by various proteins, which exhibited varying degrees of protective action. It was applied to the cerebro-spinal fluid in 1912 by Lange,[18] whose object was to ascertain the exact nature of the substance precipitated by half saturation with ammonium sulphate. He found that certain pathological fluids, in which he had expected a protective effect, exhibited, on the contrary, precipitating properties. He introduced the test as a specific and delicate one for neurosyphilis, and concluded that the reaction was due to the presence of different proteins. Numerous other workers have thought that specific proteins were responsible for the different zonal reactions and, as Cruickshank[19] points out, obviously confuse Zsigmondy's work on protective colloids with the precipitating action of the spinal fluid. In 1917 Felton[20] stated that the reactions were dependent on the relative amounts of globulin and albumin, the globulin having a precipitating and the albumin a protective action, zonal reactions being due to the inter-relationship of the two substances. Cruickshank,[19] in 1920, also came to the conclusion that the reaction depends upon relative amounts of globulin and albumin, the globulin having a special activity associated with a positive electric charge. Mellanby and Anwyl Davies[21] concluded that the precipitating power of the cerebro-spinal fluid rests in euglobulin, and that pseudo-globulin has a protective effect on the gold.

In postulating such theories many writers appear to ignore the fact, which has been emphasised by Miller and Levy,[22] that the exact nature of the substance precipitated by half saturation with ammonium sulphate, and the precise relationship between the proteins of the cerebro-spinal fluid, normal and abnormal, are as yet undetermined.

A merely superficial knowledge of the gold test in nervous diseases would appear to render untenable the theory that the various zonal reactions depend upon different amounts of albumin and globulin. Thus a high percentage of cases of disseminated sclerosis show a positive gold-curve when no globulin can be demonstrated in the cerebro-spinal fluid, while conversely in 40 per cent. of cases of cerebral tumour, for example, there is marked excess of globulin and a negative gold-curve.

The mechanism of the colloidal gold reaction was investigated in experiments involving dialysis and electrolysis, using 380 fluids giving positive gold-curves from various types of cases. By this means electro-positive and electro-negative colloids were separated and a series of tests carried out with fluid obtained from the anode and cathode respectively.

These experiments proved that globulin so collected is quite inactive in producing a positive gold-curve. The precipitate obtained by half saturation with ammonium sulphate was separated by centrifuging, dissolved in saline, and the ammonium removed by dialysis. It was found that in fluids giving a positive Wassermann reaction the precipitate so obtained had the power resembling that of the original fluid, of giving a positive gold-curve. In fluids from other diseases, including encephalitis, disseminated sclerosis, and meningitis, in which the globulin reaction was positive, it was found that this is not necessarily the case, this power frequently being completely lost. These experiments led to the conclusion that, although in some fluids, in particular those giving a positive Wassermann reaction, the gold-precipitating substance might be attached, possibly physically, to the globulin, it has no connexion with the globulin beyond this. In most of the cases of disseminated sclerosis examined it was found that the substance precipitated by ammonium sulphate, if such were present in the fluid, could be completely removed without the gold-precipitating power of the fluid being altered. In another series of fluids giving negative gold-curves and positive globulin reactions, the precipitate obtained by half saturation with ammonium sulphate was completely inactive as regards precipitating power. Thus although it is possible that the agent responsible for the reaction may, in some cases, be associated with the substance which gives a positive globulin reaction, or may cause a specific alteration in the physical state of the globulin, yet there is no evidence in these experiments to indicate that the precipitating substance is of the nature of globulin or other protein.

These results led ultimately to the conclusion that the specificity of the gold-curve, in various diseases, can only be explained on the theory that the particular form of curve must be related to the causal factor of the disease in question. If this theory is correct, one might expect that a type of curve similar to that in the cerebro-spinal fluid might be obtained in the blood serum of the same patient, since presumably this same causal agent would be present in the blood as well as in the cerebro-spinal fluid. Observations recorded in previous work on serum in this respect appear to be of little value, for neither the time elapsing after withdrawal of the blood nor the relative quantities of the various proteins present were taken into account. In order to compare the gold-curve in the cerebro-spinal fluid with that of the serum it is necessary to dilute the amount of protein in the latter so that it becomes equal to that of the cerebro-spinal fluid. Otherwise there is another factor which will obscure the true interpretation of the experiment. As is well known, serum itself will cause precipitation of colloidal gold. The type of curve obtained by serum alone depends upon the interval elapsing between withdrawal of the blood and performing the test. Taking this factor into account, control experiments were done on normal human serum, diluted as above described. The results so obtained were compared with those in which serum, similarly treated, from patients whose cerebro-spinal fluid gave a positive gold reaction, was employed. In the latter group of cases it was found that when globulin is removed from both the cerebro-spinal fluid and serum, the filtrate gives a similar type of gold-curve. In both cases initial and maximal precipitation occurred in the same tubes, so that the type of curve produced was similar. Therefore, it was concluded that the factor responsible for the gold-curve is present in the blood as well as in the cerebro-spinal fluid, and that it is independent of the globulin in each.

Hence it seemed probable that the gold-curve in various diseases is related in some way to the causal factor, toxic or otherwise. This theory is supported by the observation that the gold reaction may be positive in the cerebro-spinal fluid in cases of syphilis even when the nervous system is not involved, and in cases of pernicious anæmia before symptoms of subacute combined degeneration are present.

It has already been pointed out, in discussing the pathological aspect of the problem, that the histological evidence is in favour of a toxic origin of the disease. These experiments on the colloidal gold reaction appeared to support this view. The question arises as to the source of such a toxin and whether, if such exists, its action can be demonstrated in any other part of the body.

In an attempt to ascertain whether such a toxin existed, an investigation of the liver functions of patients suffering from disseminated sclerosis was carried out. In 64 out of 86 cases examined, the glycuronic acid test was completely negative after the administration of aspirin. Further, in these patients there was indicanuria, the average amount of indican being 10 to 12 times the normal amount.

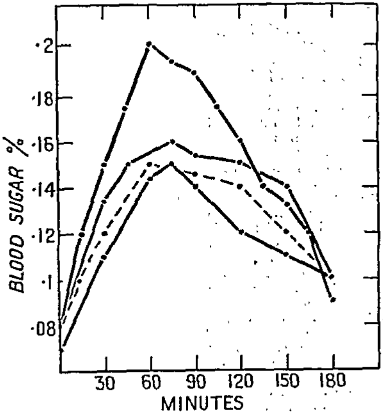

Chart showing type of blood-sugar curve obtained during lævulose-tolerance tests in patients with disseminated sclerosis.

Finally, lævulose-tolerance tests were carried out. It was found that 60 of these patients gave abnormal curves. H. MacLean's method was employed for the blood-sugar estimations which were done every 15 minutes in some cases and every 30 minutes in others, for three hours. Reference to the accompanying chart will show the type of curve obtained. It will be seen that the difference between the fasting and highest values in these curves exceeds 0·05 per cent., that the highest point of the curve is not obtained for 60 to 90 minutes, and that there is a delay in return to the original level. The results of these glycuronic acid, indican, and lævulose-tolerance tests led to the conclusion that in a high percentage of cases of disseminated sclerosis there is deficiency in the antitoxic and metabolic functions of the liver.

The question arises whether the ætiological factor is responsible for such loss of detoxicating power, or whether, owing to this deficient detoxicating mechanism, this factor is able to gain access to the body. In either case, it seemed probable from these experiments that there is a toxic factor to be taken into account in disseminated sclerosis, whether this be primary or secondary to some ætiological agent.

In discussing the possibility of the existence of autogenous or exogenous toxins, it was emphasised that none of these factors could be more than predisposing causes in the production of the well-defined clinical and anatomical picture characterising disseminated sclerosis, and that there must be some specific determining causal factor. Correlating cultures. They are killed by a 0·5 per cent. solution of carbolic acid, and are inhibited by 5 per cent. solution of glycerol.

The cultures are excessively sensitive to changes in reaction. This sensitivity is one of the difficulties of cultural experiments. The pH of the medium must be not greater than 7·6 or less than 7·5 when cultures are initiated.

It has already been emphasised that no growth visible to the eye is ever present in solid or liquid cultures. Slight opalescence is frequently seen in liquid cultures. This is probably due to changes occurring as the result of growth.

The early experiments already described in this paper demonstrated that a change of reaction occurs when cerebro-spinal fluid from cases of disseminated sclerosis is cultured under certain conditions. This experimental observation was now more fully investigated. It was found that in an actively growing culture the production of acidity is progressive until about the fifth day, and then an alkaline reversion begins. Reference to the Table, illustrating a few of the experiments carried out in this connexion, will show the type of results obtained. Although a pH of 7·6 is essential for the initiation of a culture, yet when a certain stage of the culture is attained growth can be maintained, even though the pH has fallen to 7·0. All the pH determinations in this work have been carried out by the electrical method, using a hydrogen electrode. The cause of the production of acidity, and subsequently alkalinity, has not been fully ascertained. That it is a direct result of the growth of the virus is proved by the fact that it occurs only in actively growing cultures, but the exact mechanism of the change remains a problem for future investigation. The results of these experiments, however, were regarded as additional proof that the appearance seen in cultures can only be due to a living virus.

Important confirmatory evidence of this conclusion was obtained by experiments in which sugars were added to cultures in various stages of their development. There are particular difficulties in carrying out sugar reactions in this work. The first, and most obvious, is that the usual sugar reaction medium (peptone water) cannot be used, since the virus will only grow in a mixture of Hartley's broth and serum. It was ascertained that the latter were sugar-free, and careful comparison with controls was, of course, necessary. The interpretation of the tests with glucose depends essentially on such controls, for there is the additional factor of a glycolytic ferment in the serum to be taken into account. The possibility of the influence of such a ferment in cerebro-spinal fluid can be avoided by subculturing and using subcultures for the experiments. This method, however, does not overcome the difficulty in the case of serum, since it is necessary when making a subculture to add human serum. The glycolytic ferment might be destroyed by heat were it not for the fact that serum so inactivated is unsatisfactory for cultures. Hence the only way in which the test can be carried out in the case of glucose is by comparing the results with carefully made controls. In such control tubes slight breakdown of the sugar, with consequent slight increase in acidity, occurs. The extent of this change is not comparable with that occurring in the cultural experiments.

The sugar solutions used were sterilised by filtration through Berkefeld filters to avoid sterilisation by heat. The sugar was added to the culture so that it was present in a concentration of 1 per cent. The indicators used in this work were bromcresol purple (pH 5·2 to 6·8), bromthymol blue (pH 6·0 to 7·6), and phenol red (pH 6·8 to 8·4), but for accurate determination of the changes, the electrical method for determination of hydrogen-ion concentration was employed.

In no case was any gas formation observed, but in the cases of glucose, fructose, and mannitol there was production of acidity. The reaction of cultures to which glucose has been added begins to change in 12 to 24 hours. In the cases of mannitol and fructose no change of reaction is apparent until 36 to 48 hours, or even longer, have elapsed. A pH of about 6·5 is ultimately reached, seven to ten days after the initiation of the experiment. The reaction then remains stationary and there is no return to a more alkaline reaction, as occurs with living cultures. The Table illustrates these points.

If at the end of the fifth day, when reaction is about 6·9, cultures are examined microscopically, they will be found to be negative, and no growth can be obtained in subcultures. Therefore, although the virus itself may be responsible for the initial changes in the process it cannot produce the ultimate result, and further change of reaction must be due to some other factor.

Detection of the products of fermentation remains a problem for future research. It is obviously complicated by the fact that the virus itself induces changes in the medium, as evidenced by the changes of reaction in cultures, already described.

It may be mentioned in this preliminary communication that in no case could the original glucose, fructose, or mannitol be recovered from the cultures in which this production of acidity occurred.

Filtration.

It has already been indicated that various stages of development can be observed in slip cultures examined at varying intervals of time. An attempt was now made to determine whether the appearances observed were stages in the life-cycle of a virus. For this purpose filtration experiments were carried out. In view of the inadequacy of ordinary filtration methods, ultra-filtration has been resorted to. Until recently no method of standardising filters in quantitative terms had been evolved, so that the definition of what is meant by a filter-passer is uncertain. It has been pointed out by numerous workers that filtration through filters of the Berkefeld or Chamberland type is unreliable. A filter is not a mere mechanical sieve, and several factors other than the size of the filter-pore determine whether a given body will pass through it, and influence the results of filtration experiments. In this research collodion membranes have been used with a known size of pore, this being determined by the concentration of collodion used in the production of the membrane. These collodion membranes were kindly supplied by Mr. Elford, working at the National Institute for Medical Research. The method of preparation of membranes and the technique employed are described in a paper by Elford.[25] These ultra-filtration experiments are as yet incomplete, and will form an important part of future investigations. It may be mentioned in this preliminary communication, however, that when a certain grade of membrane was used, it was found that the filtrate contained granules only. The filtrate so obtained was inoculated into serum-broth, incubated at 37° C., and from this culture 24 hours later slip-cultures were made in the usual way. In such slip-cultures the characteristic appearance of spheres and granules was obtained 24 to 36 hours later. The inference drawn from these preliminary experiments is that spheres can be produced from the granules in cultures.

The correlation of these various experimental results led to the conclusion that, under certain conditions, a living virus can be cultured from the cerebro-spinal fluid from cases of disseminated sclerosis. The cerebro-spinal fluids of 188 cases of this disease have been cultured and examined in this way. In 176 of these cultures the characteristic appearance described was observed. These cases included patients undergoing a so-called spontaneous remission occurring in the course of the disease, as well as those stationary or clinically advancing. Hence this appearance was specific in that it could be demonstrated in such cultures, but was invariably absent in controls.

Many samples of uncultured cerebro-spinal fluid from these patients have been examined according to the microscopical technique described, but in no case have any spheres or particles ever been observed. This may be because the virus is not present in sufficient quantity, or exists in some form which cannot be seen by such a method. It may be due to lack of optical contrast between the virus and its surroundings, that is, to insufficient difference of refractive index between the virus and the medium in which it is immersed. Cultures of the blood serum of such patients have been uniformly negative, and if at any stage of the disease the blood be infective, such a stage has not been detected in this work.

Cultures of cerebro-spinal fluid from 209 control cases have been examined by this method and proved to be completely negative in this respect. These control cases include normal cases, hysteria, tabes dorsalis, cerebro-spinal syphilis, subacute combined degeneration of the cord, transverse myelitis, spinal compression, epilepsy, cerebral tumour, and encephalitis.

As regards the method of cultivation, it has been emphasised that reliable results can only be obtained by the use of normal human serum. Serum from patients suffering with disseminated sclerosis cannot be used *for this purpose. Such serum cannot be* described as being inhibitory to the growth of the cultures, but simply acts like any other unsuitable serum, such as that of goats, rabbits, monkeys, and guinea-pigs. Horse serum can be used as a substitute, but it is unsatisfactory. The cultures take much longer to develop, and the only reliable way in which characteristic cultures can be obtained is to use normal human serum.

In the preparation of cultures, it is preferable to receive the cerebro-spinal fluid directly into the culture medium. If this is not done, the time elapsing between withdrawal and culturing of the fluid must be very short, otherwise growth cannot be obtained in cultures. In this connexion it may be mentioned that transference of the material, either before culturing or before microscopical examination of the cultures, is very undesirable. Such a procedure leads to unreliable and inconstant results, although the reason for this is not, at the moment, perfectly clear.

The cerebro-spinal fluid must be withdrawn under strictly aseptic conditions. Unless particular care is exercised in this respect bacterial contaminations, which so easily occur, not only obscure the microscopical appearance but prevent growth of the virus and so render the culture useless.

It was recognised that if the virus described is the causative agent of disseminated sclerosis it might presumably produce a specific effect on myelin. Such an action might be due to the virus itself or the result of some product of the virus. The investigation of this possibility has been carried out by Dr. Hocking, and is described by him in a paper which follows.

It has already been pointed out that there is evidence of a toxic factor in disseminated sclerosis. In discussing the significance of the results which led to this conclusion, it was emphasised that if a toxin exists as an ætiological factor, it must be elaborated from a highly specific source, in view of the clearly defined clinical and anatomical features characterising disseminated sclerosis. The question arises what is the relationship of the virus to this toxic factor. Evidence that such a relationship exists is afforded by a study of the cultural properties of the cerebro-spinal fluid and its capacity to produce a positive gold reaction. Thus it has been found that in all cases of disseminated sclerosis, in which colloidal gold test was positive, the virus could be cultured from a sample of cerebro-spinal fluid taken simultaneously. It has been found that if on a subsequent occasion a sample of cerebro-spinal fluid from the same patient yielded negative cultures the gold-curve had also become negative. This observation was confirmed so often that it must be concluded that there is some relationship between the factor responsible for the precipitation of colloidal gold and the presence of the virus in cultures of cerebro-spinal fluid. It is evident that this factor cannot possibly be related directly to the presence of the virus. Cerebro-spinal fluid will, of course, precipitate colloidal gold many hours after withdrawal when it can no longer be used to obtain cultures of the virus. Neither is the converse relationship necessarily true, for the gold test may be negative in cerebro-spinal fluid from which positive cultures can be obtained. Hence, although a correlation of the colloidal gold reaction and cultural results shows a definite connexion in this respect, the precise relationship has not been determined. It is conceivable that the factor responsible for precipitation of the gold results from some product, toxin or otherwise, of the virus. This possibility will be investigated in future research.

An attempt has been made in this preliminary communication to show how the problem of the ætiology of disseminated sclerosis was investigated in the light of the evidence provided by the histological observations of previous workers, and that afforded by the results of the colloidal gold and liver function tests carried out in this research. A simple experiment, designed to discover whether or not anything of the nature of a living organism was present in cultures of cerebro-spinal fluid, gave important results which suggested that such might be the case. The correlation of these experiments led to a fuller investigation of the subject, and to the use of a method which previously had not been employed for the examination of material from cases of disseminated sclerosis. A characteristic appearance, specific in that it can be obtained only in cultures of cerebro-spinal fluid of cases of disseminated sclerosis, is seen by employing a certain technique.

The following experimental observations support the theory that this appearance is due to a living virus.

1. Multiplication in vitro occurs.
2. Subculturing can be effected.
3. Sensitivity to hydrogen-ion concentration, temperature, and certain chemical agents is manifest.
4. Sugar reactions, at least in their initial phases, are induced by actively growing cultures, although subsequently they may be due to some other factor.
5. Changes in the hydrogen-ion concentration of the medium results from, and is associated with, growth of culture.

It will be evident that the appearance of the cultures described bears a striking resemblance to the organism which is regarded as the causative agent of bovine pleuro-pneumonia. The latter is of particular interest because it appears to be a connecting link between ordinary bacteria and those known as filtrable viruses. Pleuro-pneumonia is the smallest organism known to grow under ordinary bacteriological methods of cultivation. It is a small particulate body of about 0·2μ diameter. The particulate form is accompanied by and is dependent for its reproduction on a larger spheroidal body which develops from the particulate form.[24] The results embodied in this paper have led to the conclusion that a similar sequence of events is to be observed in cultures of cerebro-spinal fluid from cases of disseminated sclerosis. In both cases varying phases occur, the small granular form being associated with other bodies of essentially different characters.

Except for the virus of pleuro-pneumonia, cultivation of filtrable viruses has not yet proved possible in the absence of living cells. It is clear that until cultures can be made in an artificial medium and separated from cellular material, progress in their study is hindered by the presence of many uncontrollable and undetermined factors. In this research, however, such conditions have been more nearly attained, since it is necessary to add human serum only to the medium.

It has been suggested by many authorities that filtrable viruses are not of the nature of living organisms, and that enzymes or ferments may produce the observed results. Power of multiplication alone is not necessarily proof of life, neither is sensitivity to hydrogen-ion concentration or temperature. No organism belonging strictly to the group of filtrable viruses has yet been observed with sufficient accuracy to enable a description to be given of its cultural and morphological characteristics. It would appear, however, that a study of the virus described in this paper survive. Hence the importance of recognising and treating the disease in its earliest stages, when the neurones are merely poisoned but not yet degenerated. Fortunately, combined clinical, serological, and bacteriological examinations now enable us to diagnose such cases at an earlier stage than was formerly possible.

Summary.

1. A filtrable virus (*Spherula insularis*) has been observed and cultured by Miss K. Chevassut from the cerebro-spinal fluid in 176 out of 189 cases of disseminated sclerosis.

2. In a control series of 269 cases of other nervous maladies, organic and otherwise, no such organism was observed.

3. Cultures of this virus have been inoculated in a small series of seven monkeys. One of these monkeys developed paralytic symptoms and examination of its spinal cord by the Marchi method shows tract degenerations in one posterior column and one direct cerebellar tract. A second monkey shows degenerations in one antero-median and in both lateral columns.

4. Experimental treatment by an autogenous vaccine has been carried out in a series of 128 cases of disseminated sclerosis; 70 of these patients have been under observation long enough to yield suggestive results. Four illustrative examples are quoted.

5. In a few cases the patient's blood-serum, after vaccine treatment, developed an inhibitory action upon the growth of the spherula *in vitro*.

6. The clinical results, so far, may be summarised as follows:—

Out of 10 early cases, 9 improved and 1 remained in statu quo.
„ 27 moderate cases, 22 improved and 5 not improved.
„ 33 advanced cases, 9 improved and 24 not improved.

7. The serological observations, so far, yield the following results:—

Out of 10 early cases, 4 developed negative cultures; 8 showed improvement in the gold and globulin reactions.
Out of 27 moderate cases, 4 developed negative cultures; 21 showed improvement in the gold and globulin reactions.
Out of 33 advanced cases, in no case did the cultures become negative, whilst in 20 there was improvement in the gold and globulin reactions.

8. In assessing the value of any treatment special caution must be exercised, in view of the well-known tendency of disseminated sclerosis to undergo spontaneous remissions.

9. Degenerations within the central nervous system are a permanent affair and regeneration does not occur. The most that can be hoped for, in any form of treatment, is to arrest the malady at the stage which it has already reached and to make the most of those nervous structures which survive. Restoration of degenerated nervous tissues to normal is not to be expected.

I beg to tender my grateful thanks to many of my colleagues at Westminster Hospital for their continuous kindly encouragement, and for their courtesy in sending me patients for experimental treatment. Especially am I indebted to Dr. D. H. de Souza, Dr. A. S. Woodwark, Dr. A. W. Stott, Dr. Adolphe Abrahams, and Dr. W. E. Lloyd.

A CASE OF
CALCIFICATION OF THE PERICARDIUM.

BY G. E. VILVANDRÉ, M.R.C.S. ENG.,
ASSISTANT RADIOLOGIST TO THE LONDON HOSPITAL.

(WITH ILLUSTRATIONS ON SPECIAL PLATE.)

A CASE of calcification of the pericardium was discovered in the course of an opaque meal examination of the stomach. The condition is rare, as shown by the published cases to which I shall refer.

The patient, a woman aged 67, was admitted to the London Hospital under Mr. Hugh Lett, and gave a history of attacks of pain in the upper abdomen, nausea, and vomiting every week or two for 12 months. The attacks were said to last from two days to one week, and they had no relation to exertion. Pain was felt in the right scapular region and down the right side, but was never severe. Freedom from attacks might last seven weeks. There was an indefinite history of indigestion since the menopause. In her previous history mention was made of several attacks of influenza and bronchitis. She had never had rheumatism, chorea, pleurisy, or pneumonia. Up to five months before admission she could walk a couple of miles and enjoy the exercise; she had never been short-winded. Because of her gastric history, she was referred to the radiological department for a barium meal examination to confirm a diagnosis of gastric ulcer.

Radiological Examination.

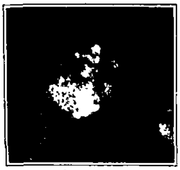
Before the ingestion of barium the heart appeared strikingly denser than normal. The greatest density was at the right auricular border and along the diaphragmatic border. Where the two joined a sharp angle was formed. Absence of the normal smooth contour of the right auricle was obvious. No pulsation was visible and the aorta was normal. Less evident, but definite, were patches of calcium scattered over the cardiac shadow, but almost absent over the apex. The apical portion of the heart—and this only—was seen to pulsate strongly and freely and to stand out in contrast with the rest of the denser calcium-covered pericardium where no pulsation was visible. The appearance suggested that the strong muscular apical contraction might have interfered with the formation of calcium deposits in that region. The heart as a whole scarcely moved with respiration. On the screen the cardiac apex looked like a living shadow, protruding out of an immovable casing with every pulsation. Some movement of the diaphragm was seen. The lung fields were clear. Slight scoliosis was also present.

Barium fluid given for the examination of the stomach showed no gross deviation of the œsophagus nor any delay, and no obvious radiological evidence of mediastinitis. The gastric examination revealed a definite ulcer near the pylorus, and the general appearance of the pars pylorica suggested carcinomatous changes. The radioscopic gastric findings were confirmed at operation. The pericardial calcification did not cause any untoward result from the anæsthetic or operation, and the patient left the surgical ward in about a fortnight. It seems therefore that in this case, as in some others, the pericardial condition was consistent with fair general health, and the heart worked successfully, even under the strain of anæsthesia and serious abdominal operation. The condition had been totally unsuspected clinically, had given rise to no clinical symptoms or signs, and had apparently not made any difference to the patient's life. It had no connexion with her gastric illness.

Films of the chest (see Plate, Figs. I.–III.) show *the obvious calcification of the pericardium*, denser in the region where a thick purulent fluid would settle by gravity, and curiously absent or less evident in the region of greatest cardiac impulse, the apex of the left ventricle. There was complete absence of pulsation at the right auricular border, and this suggested fixation (adherent pericardium).

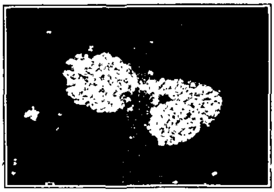
MISS K. CHEVASSUT: DISSEMINATED SCLEROSIS.

FIG. I.



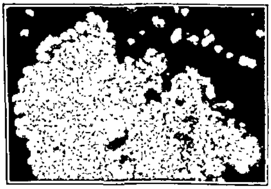
Photomicrograph of a colony, from a culture of cerebro-spinal fluid from a case of disseminated sclerosis.

FIG. II.



Two groups of spheres and granules, from a culture of cerebro-spinal fluid from a case of disseminated sclerosis.

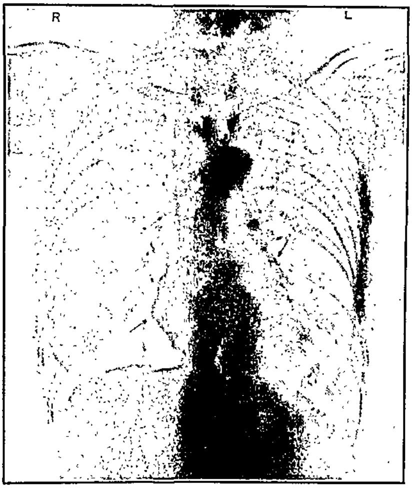
FIG. III.



Large degenerating colony, from a culture of cerebro-spinal fluid from a case of disseminated sclerosis.

DR. VILVANDRÉ.

FIG. I.



Anteroposterior teleradiogram taken at 2 metres' distance with patient standing.

FIG. II.

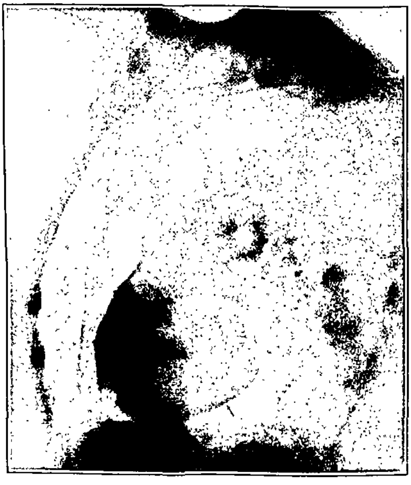


FIG. III.

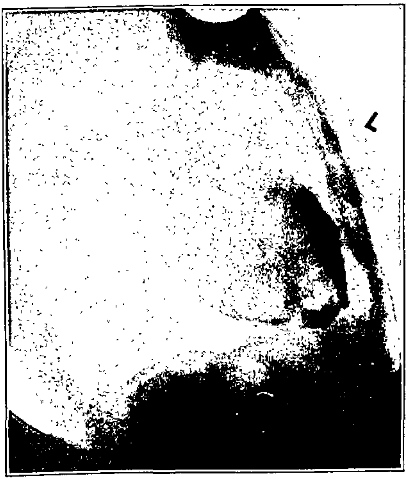
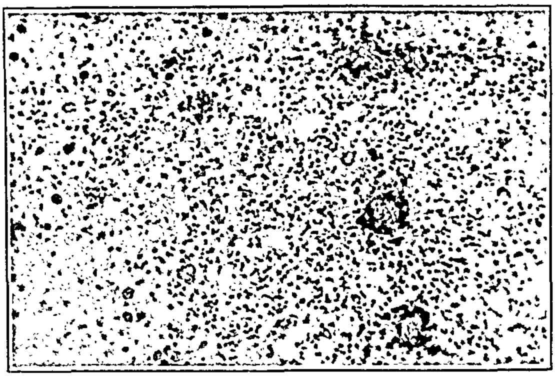


Radiograms of chest, taken in right semi-lateral position and in left lateral position.

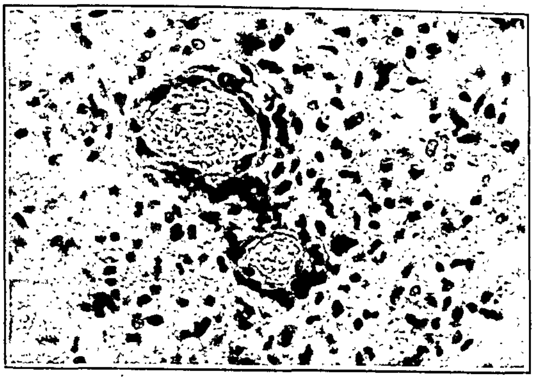
DR. VILVANDRÉ: CALCIFICATION OF THE PERICARDIUM.

FIG. I.



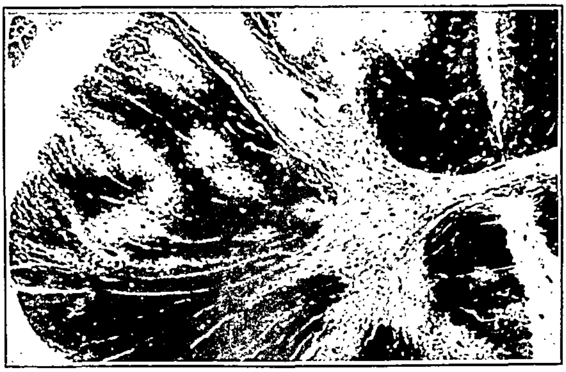
Low-power photograph of the spinal cord, showing the extra-adventitial infiltration around a group of vessels. Note the numerous large spaces in the tissues.

FIG. II.



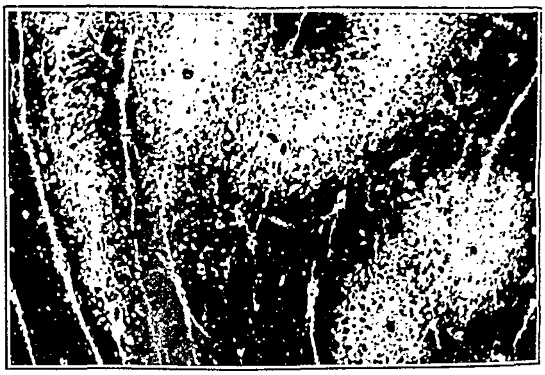
High-power view of the extra-adventitial infiltrate to show the character of the cells present. Perivascular infiltration, chiefly with fat granule cells, is also seen.

FIG. III.



General view of the spinal cord stained by the Weigert-Pal method to show the wide zones of demyelination around the vessels.

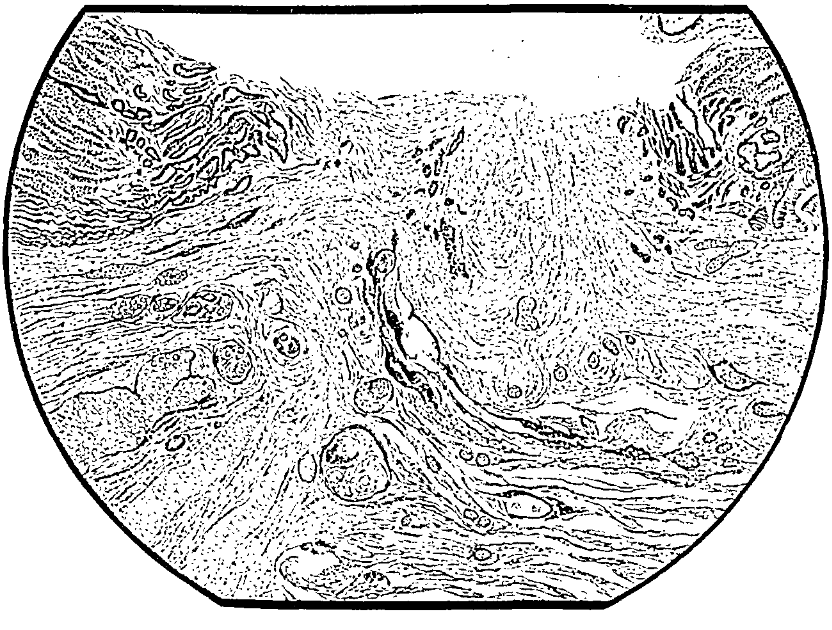
FIG. IV.



Weigert-Pal preparation of the spinal cord showing complete demyelination in the areas immediately around the vessels and partial demyelination in the zones peripheral to these.

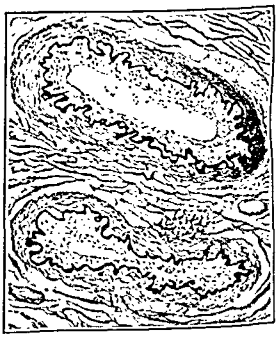
DRS. TROUP AND HURST: ENCEPHALOMYELITIS FOLLOWING SMALL-POX.

FIG. II.



A section through the ulcer × 10. At the margin the tumour can be seen invading the muscle coat. The ulcer is denuded of mucous membrane and is composed of fibrous tissue. A few tumour acini can be seen invading it from below.

FIG. III.



Arteries in the base of the ulcer showing endarteritis × 50.

PROF. KETTLE: MALIGNANT DUODENAL ULCER.

Clinical Examination.

Dr. John Parkinson kindly saw the patient with me a month later. Though rather wasted, she was cheerful and of good colour. The pulse was normal and the superficial arteries were not thickened. The veins of the neck were a little full, but showed no undue pulsation and no collapse. The apex-beat was of natural force and normally placed. The heart sounds were normal at all areas and no murmurs were heard. The electrocardiogram (Fig. IV.) showed a normal rhythm; in lead II. the auricular wave P is rather large, and T is flat, otherwise the curve appears to be normal. There were no symptoms of cardiac distress, and no signs of heart failure. Without the radiological discovery there seemed no reason, from the history or examination, to suspect any cardiac lesion.

Previous Literature.

Case,[1] up to 1923, had found only 13 instances of a diagnosis of pericarditis calculosa (concretio pericardii) made during life. In July, 1924, Cutler and Sosman[2] added three, two of which were confirmed post mortem. In these two calcification of the endocardium and myocardium was also found at necropsy. They suggest that if calcification could be demonstrated in cases of suspected adherent pericardium there would be greatly increased evidence in favour of that diagnosis. They quote Wells who, in 1000 necropsies, found calcification in 4 out of 128 cases of adherent pericardium. Calcification of the heart itself is well known to pathologists. Scholz,[3] in 1924, described a case of myocardial calcification accidentally found post mortem. He mentions that Morgagni in 1762 published a case of calcification of the heart. Bordenare, in 1768, described a case of adhesive pericarditis and myocardial calcification found at necropsy. Samuel Foart Simmons and Henry Watson, in 1783, published a case of myocardial calcification with an illustration. In their case the patient had died of carcinoma of the œsophagus which, when he was admitted to the Westminster Dispensary, dominated the clinical picture. Watson attempted to explain the calcification, but to him atheroma and myocardial calcification were apparently one. Roth, in 1884, published an autopsy showing calcification of the heart walls, the kidneys, and the interstitial tissue of the gastric mucosa (see Scholz). In 1906 Leyden and Dairdsohn published a report of another necropsy in which there was evidence that calcification of the heart may be part of a calcium metastasis, and that in such cases lungs, kidneys, and stomach form the places of predilection for the deposition of calcium, on account of their abundance of oxygen and acids. In 1907 Hedinger (quoted by Scholz) said that heart calcification was explained by some on the basis of myocardial degeneration, necrotic foci being found by the side of calcified areas, and in the same year Weichert, reporting a similar case (myocardial calcification), looked upon the condition as secondary to myocardial degeneration of bacterial origin.

Mueller (Turner[4]) does not believe that the calcium deposit is due to an increase of the proportion of calcium in the blood, but that a most minute amount is present in each living cell. When the cell dies the calcium is liberated as a carbonate or phosphate and is then precipitated. The causes of pericardial calcification are given as rheumatic or inflammatory chest conditions, pericarditis, or pleurisy. Aneurysm was associated with it in one case, and rupture of the femoral artery in another, and in two separate instances rupture of the coronary and rupture of the right auricle (Turner).
